Parmi les perfectionnements qui ont été déjà réalisés, paraît-il, par M. Edison, nous en indiquerons un seul. Dans de nouveaux appareils, le papier d'étain se place non plus sur un cylindre, mais sur une plaque dans laquelle on a tracé une rainure qui a la forme d'une spirale d'Archimède, ou pour parler le langage vulgaire, la forme d'un limaçon; le mouvement de cette plaque est combiné de manière que le style puisse parcourir la membrane tracé ses inscriptions dans la rainure de la spirale. Cette disposition est

certainement plus compliquée que celle qui a été montrée à Paris; mais elle permet de placer plus aisément et plus promptement la feuille d'étain et surtout elle permet, la feuille une fois écrite, de la placer sur un

Baillie, Captain William, 45, Norfolk-square, Hyde-park, W., and Dunsmore, Gravesend.
Lean, George, 19, Gloucester-place, W.
Mackay, Alexander, 3, Bolt-court, Fleet-street, E.C.
Mottram, Henry Wilton, F.R.G.S., Guernsey-lodge, West-end, Hilburn, N.W.
Smithers, Theodore, F.L.S., J.P., Beckwood, Nantwich, Cheshire.
Thornhill, John B., Bradford, Manchester.

The following candidates were balloted for and duly elected members of the Society:—

Addy, Jas., Peterborough.
Hiscock, Charles Henry, 19, Alexandra-road, Southport, Lancashire.
Hurlstone, George Thomas, Lord Chamberlain's office, St. James's Palace, S.W.
Jones, William Henry, 126, Mottram-road, Stalybridge.
Lowe, Col. Army Clothing Department, Pimlico, S.W.
Morton, Emile H., 56a, Piccadilly, W.
Remmington, Sir James, Barrow-in-Furness, Lancashire.
Styles, Thomas H., Cringle-house, Cheadle, near Manchester.
Wilkinson, M. A. Bazeo, M.D., F.R.C.P., Greenhays, Manchester.

The paper read was—

THE PHONOGRAPH.

By W. H. Preece.

The science of acoustics has taken most marvellous strides within the last few months. We have already had in this room a description of the telephone itself. We have, in addition to that, another instrument that has created a great deal of sensation, and which I shall have the pleasure of bringing before you to-night. But besides the telephone and the phonograph, there are other wonders in store. Thorpe's an instrument—which has not yet come from the other side of the Atlantic—called the seraphone. The seraphone is an instrument that combines the violin to be heard at a distance of four miles. On the other hand, we have within the last few days produced in England an instrument that will be brought before the Royal Society, the microscope again, which enabled the microphone. The microphone is an instrument which sets towards the ear as the microscope does to the eye. It will render evident to us sounds that are otherwise absolutely inaudible. We have heard myself the tramp of a little fly across a box with a tread almost as loud as that of a horse across a wooden bridge. There was a remarkable sound that accompanied the tramp of Mr. Fly, and a facetious friend of mine told me he thought the noise was occasioned by the weighing of the proboscis of the fly. Between the microphone on the one side and the seraphone on the other, we have accomplished a middle position, the instrument I have to bring before you to-night. All these instruments depend upon the operation of that marvellous agent, the electric current, which we call sensitive. If I ring a bell, blow a musical instrument, or strike anything, what is it that has happened, which passing from me to everybody's ear in this room has produced that all anxious to say the phonograph is operating, but I think it is just as well to make you acquainted shortly with the principles on which the phonograph works, for then you comprehend the principles, you will, to an infinitely greater extent, admire the instrument itself. So let us ask ourselves, what is this thing which we call sound? Sound of any kind is reducible, to motion. The motion of matter is necessary and essential for the production of sound, and the motion of the air, the air that surrounds us and which we breathe, that bathes everybody in this room, is essential for the production of that operation which is now taking place in my throat. I am rather sorry to find that it is still daylight to a certain extent, but I am in hopes if the gas is put down I shall be able to give you a little notion of what sonorous vibration is.

Our notion of waves is derived from what we see upon the water; we see there a motion of smooth and descent, accompanied by a motion of translation, but in this room, although at the present moment, while I am speaking to you the air is chased and engraved in the most exquisite manner by the undulations I am imparting to it, all this is invisible to us, and it must so remain. All that we can do is to give you a faint conception of how this air acts. If you could see a tube of air, for instance, coming from my mouth to any one of your ears, then that tube of air, by every sound that is uttered, is thrown into vibration. But it is not a vibration of secret and concealed like the waves of the ocean, but it is an excursion to and fro, and between me and the end of the room, for every sound I utter there is in every particle of air an excursion to and fro. Now, notice or sounds vary in three particular ways.

In the first place, we have the pitch of a note. The pitch of a note is that which determines whether it shall be A, B, or C, or any other note of music; and the pitch of a note is due to the number of vibrations that are made per second, or, in other words, the length of the wave. So that the first property connected with notes is that of their pitch, and their pitch depends upon the length of the sonorous wave.

The second property of sound is that of loudness. I can speak to you softly, I can speak to you aloud, you can hear the note of a piano gently played, you can press the pedal, and you can hear it loudly played. You can produce sounds that vary in intensity between great extremes, and the sonorous wave sound is greater than another is, that the amplitude of the excursions of particles of air are greater in one case than in the other; in other words, their velocity being different from the velocity of the ear with greater force. In the same way, if you take a common smooth-bore gun a few feet, and you take an Armstrong gun, which differs the ball with a velocity of 1,500 feet, in the one case you have the ball making an indentation, in a metal shield, while in the other case you have the ball went right through the shield. So when you utter sounds softly, the tympanum of the ear is struck gently; and when you utter sounds loudly, the ear is struck with greater force. The loudness of sound is dependent upon the amplitude to and fro of the particles of air.

But there is a third property of sound, which is distinguishes one voice from another, that distinguishes the note C on the violin from the same note on the piano; the cause of the difference between the sound of the drum and a cornet, and all the difference that occur between various sounds. All these differences are solely dependent upon the form in which the waves take their excursion to and fro. They may jerk to and fro, they may move gently forward and back again, with a high velocity or a low velocity, and as they may vary their mode of excursion to and fro in innumerable most and produce various shades of intonation and articulation. So that we have, first of all, the pitch of a note which depends on the length of the wave; secondly, the loudness of a note, which depends on the amplitude of the excursion; and, thirdly, the quality of a note, which depends upon the form of the wave.

I will endeavour to give you an idea of what a sonorous wave is. On the screen you will see a little spot of light. I am not sure that the light is visible to the whole of the room, but that little spot of light is supposed to represent a particle of air now in a state of quiescence in some part of this room. If we move the slide up and down, you will see it takes a motion backward and forward, which represents very roughly the movement to and fro of the particles of air between me and the end of the room. The next slide shows a portion of the suppositious tube of air, including several of these particles, and in this I have endeavoured to illustrate to you what takes place to form a wave. A wave means a succession of lines of compression and of rarefaction. Since there is no up and down movement like the waves of the sea, but there is an excursion to and fro, which excursion results in a series of compressions and rarefactions. Now, if we move that slide up and down, you will see passing over it a series of waves, and the waves are simply a series of condensations and rarefactions. They are very regular, and after a moment I should be very sorry indeed for anybody to imagine that what you see on the screen is an actual representation of what takes place in nature. Nature is far more beautiful, but in order to make an attempt to illustrate her laws, we have nothing but what is crude and rough. It is, however, an attempt to bring before you what is taking place in this room. That shows what takes place in air, but between my mouth and my ear in this room. But there are millions upon millions of particles going through the same operations of condensation and rarefaction, which you see. When the mind attempts to fix itself upon what takes place in this air, when you endeavour to picture what is going on in nature, you become lost in the effort.

I am now going to show you how matter itself vibrates when you put it in a line of these moving particles. Here is another rough attempt to show you what really occurs, but this is not an effort to endeave you to exercise your imagination, but to show you actually what takes place when one species of matter is struck. Now, Mr. Strah has in front of him an India-rubber diaphragm, upon which is placed a mirror, and this mirror will reflect upon the screen a spot of light. You will see that, as no sounds a note, the diaphragm vibrates, giving evidence of its vibration by the motion of the spot of light. If while he sounds the note, he moves backwards and forwards, the spot of light is thrown across the screen, and you first there is an illustration of what I told you, that the note is simply dependent upon the number of vibrations per second; for, if he sounds a low note and then a high note, the difference in vibrations will be apparent to you.

I do not know whether those experiments were sufficient to illustrate to you two facts—first, that sound is produced by the vibration of the particles of air; and, secondly, that objects placed in those paths of vibrating air can themselves be vibrated. It is said that Lablache could sound a note so loud and strong that he could crack a tumbler; and in the Midland Counties there is a sergeant-major of a volunteer corps who is often brought into the room after mess to crack a tumbler in this way. So far as regards the production of sound.

Now, one or two words about the transmission of sound, before we come to the phonograph, which, doubtless, you are all anxious to see. The transmission of sound is twofold: we can have the mechanical transmission, and we can have the transmission by electrical means. In the earliest days of civilization, the ancient Greeks acquired the art of transmitting sound, and there were actors who addressed the audience through speaking-trumpets. With these they managed to put down t. e stage, directing their speeches by this means to the furthest end of the theatre. I do not think in the present day we could stand Mr. Henry Irving reciting "To be, or not to be," through speaking trumpet.

Amongst the proposals to transmit sound, there is one very interesting record of that marvellous old man, Roger Bacon, who some 300 years ago, Mr. Robert Hook, and invented what we know now as the tay telephone. He found that sounds could be transmitted round corners, and to a distance of a hundred yards, by means of stretched cord and wire. Whenever, within our memory, produced his telephone, which succeeded in transmitting from the lower to the upper regions—from the cellars of the house to the garrets—the gentle murmur of voices. Wheatstone, within our memory, produced his telephone, which succeeded in transmitting from the lower to the upper regions—from the cellars of a house to the garrets—the gentle murmur of voices. Wheatstone, within our memory, produced his acoustic telegraph, by means of stretched cord and wire

side of the Atlantic had made, and when I went there I fully expected I should have the pleasure of exposing the telephone. I had not been there long before I met Professor Bell. I saw his telephone, and I became a convert. I say mention that it was my special pleasure to be the first person to bring this instrument to England; I exhibited it at the meeting of the British Association at Plymouth, and gradually the fact has dawned upon every one, that it is possible to convey the human voice from one spot to another. Well, others have worked in this field. Edison has worked in the footsteps of Professor Bell, and as the outcome of it, he has produced the phonograph. Professor Hughes is the gentleman who has succeeded in making us hear the fly walk, and others are working in the same line. What I want you to clearly understand is this, that all these instruments, whether it be the microphone of Professor Hughes, the telephone of Professor Bell, the speaphone of Mr. Edison, or the interesting instrument behind me, the phonograph, they all depend on this one simple, wonderful fact, which, to my mind, is one of the greatest discoveries of this age, namely, that a mere vibrating diaphragm can produce all the articulations and all the variety and beauty of the human voice. I am sure there is scarcely a man in England who would have believed six months ago that it was possible for a diaphragm of thin hard to reproduce the human voice. Certainly, men like Sir Charles Wheatstone and others, who described the best part of their lives to perfecting the speaking instrument, would have thought us stark staring mad if we had told them that the whole beauty of the human voice would ever be reproduced by a plain, simple diaphragm.

Now, in some of the instruments which I have mentioned to you, I have referred to the use of electricity and the use of magnetism, but in the phonograph, to which I am coming, we have neither electricity nor magnetism; and I want at once to destroy your minds of the idea that there is any electrical need with it, because one of the first questions which is usually asked me is, where is the magnet? There is nothing of the sort here; it is simply a mechanical contrivance. We have merely to insert a diaphragm in the centre of the concave vibrations emitted from our mouths, to produce motion. Philosophers have taken advantage of this motion to record sound, and to produce an instrument called the phonograph.

Mr. William Henry Barlow, one of our most eminent engineers, produced what is termed the logograph, that being an instrument which recorded the sonorous vibrations properly of the mouth, but the variations of the air pressure in the immediate vicinity of the mouth. On the diagrams to your right there is an enlarged representation, on Mr. Barlow's logograph, of the line, "The mistletoe bay to the war has gone—In the realm of death you'll find him." There you will see depicted the very different sounds uttered by the voice. They give you, in their angularity, the loudness of the sound; in their length, the pitch of the sound; and in the French call it. From this we come to the finder, or the phonograph, of which we have now all the elements before us. The phonograph was discovered, like many other things, by mere chance. Edison himself was experimenting with the telephone, trying all kinds of experiments, as all of us have been doing, to improve the telephone: in doing so, he pricked his finger, and, dreading it rapidly away, a kiss was made on his finger. This gave him the notion that if the diaphragm of a telephone could mark his finger, why should it not mark paper, and if it marked paper, why could the sound not be reproduced? So he took a piece of Morse paper and inserted the diaphragm of the telephone, where the ordinary style of the Morse instrument is, and there he found on the paper, when he uttered the words, "Hallo! hallo!" distinct marks—varying dots and dashes, or a series of dots. Then he took this strip of paper and allowed it to pass back again. He simply reversed the process, and instead of making the diaphragm vibrate with his voice, by passing the paper back again in the reverse direction, he caused the paper to make the diaphragm vibrate, and the result was, he heard a faint "Hallo! hallo!" come out of the diaphragm. This was a glorious triumph for Edison. It occurred on a Wednesday afternoon. He worked at it all the Wednesday, all Wednesday night, all Thursday, and Thursday night, all Friday, and Friday night unfortunately, without eating, drinking, or sleeping, until on Saturday morning he produced his first phonograph. I have on this diagram a drawing of this first phonograph. His difficulty was, having secured the principle of the vibrating diaphragm, to procure some substance which would retain those marks. By a happy inspiration he showed at once lighted upon tinfoil. Tinfoil is in itself a highly inelastic substance, and is not only very inelastic, but is a very yielding substance. Any mark made on tinfoil remains impressed there, and will remain there for an indefinite period. He then made a cylinder of brass, which he covered with a sheet of tinfoil. The cylinder was centred on a screwed axis supported by uprights, and was actuated by a handle at the extreme end. A heavy fly-wheel was attached to it to secure uniform velocity, and there you have all the mechanical contrivances required to make a phonograph. The needle in which it moves is shown in this section on the lower part of the diagram, which is a section taken through the diagram of the cylinder. It shows here the centre of the phonograph with its point behind it, the rough end of the cylinder depicts the vibrations, and the forms that are marked on the tinfoil somewhat similar to the forms that are marked on Mr. Barlow's logograph. The great difficulty that persons at first have in following the description of the phonograph is this. We can all very readily see how the vibration of a diaphragm can make marks upon tinfoil, but it is not so easy to see how it is that when you reverse the process these marks on the tinfoil reproduce or repeat the same vibrations. We fancy that the effect of reversing this process, and passing the tinfoil under the diaphragm, would be not to make the diaphragm vibrate, but to rub out the marks on the tinfoil. But the marks are not rubbed out. It appears that the resistance which the diaphragm makes to the vibrations caused by the marks on the tinfoil is very slight, and the same piece of tinfoil can be used over and over

again. I have used the same piece as many as 20 times, with a very slight difference in the intensity of sounds produced. The fact remains, that when you pass this marked tinfoil a second time beneath the point at the back of the diaphragm, it there causes the diaphragm to vibrate in exactly the same way as it vibrated under your voice, and the result is if you cause the diaphragm to vibrate in the same way that it vibrated under your voice, you get precisely the same notes, at the same pitch, and in the same quality as were contributed to it by your voice. I do not know whether I have made myself clear, but if I have not the instrument shall speak for itself. Here we have the latest form of instrument. It is made by one of the first mechanicians in this country, Mr. Stroh, for the London Stereoscopic Company, who have secured the right of using the phonograph in England, and to whose courtesy and kindness we are indebted for its exhibition to-night. It differs considerably, as you see, from the instrument I have described to you, viz., Edison's first instrument, although it is essentially the same in principle. One great defect in the instrument shown on the diagram, is that you cannot ensure the same velocity of rotation in the cylinder when the sounds are repeated as it had when the sounds were given to it. It requires great delicacy, and a great deal of experience to rotate an instrument of the kind with uniform velocity by the hand, although aided by a fly-wheel. Here, by an exceedingly pretty contrivance, there is a fusee weight, which, by an endless chain, and two or three wheels, imparts rotation to the cylinder, and it has this governor above it, those expanding wings, which, by their resistance to the air, give to the instrument what it wants, namely, uniform velocity. The result is, that when you speak into this instrument, you obtain very nearly a reproduction of the sounds emitted—very nearly, not quite. The instrument has not quite reached that perfection when the voice of a Siddons, or the speech of a Gladstone, or the sermons of a Liddon, can be faithfully reproduced; it has been exhibited as a buffoonery or parody of the human voice. You have heard me speak into it, and you have heard it; you will be able to judge how far the instrument will reproduce my own voice. It gives off musical sounds admirably, but unfortunately I am not a musician. I do not know a note of music, and I know two songs, one of which was "God save the Queen," and the other was not. I do not know the song that was not, so I will presently give you "God save the Queen," but before we come to that, we will try some poetical quotations, or some learned aphorisms, and see what the effect will be.

[Various experiments were made with the instrument, which repeated some lines of a nursery rhyme, some remarks made by the Chairman, a verse of "God save the Queen," sung as a duet, the notes of a bugle, and imitations of animals, &c.]

I dare say many of us have thought to ourselves, what uses can this instrument be put to. Now, it is quite evident to you that though the production of a voice is very wonderful, it is not very perfect: it fail, there are some consonants that are wanting altogether. The s for instance at the beginning and end of a word is almost entirely lost—is entirely lost, although it is heard slightly in the middle of a word. The d and the t are exactly the same; and the same in m and n, same and some are not distinguishable. Hence, it is extremely difficult to read what is said upon this instrument; if a person is put out of the room, and you speak into it, he can with difficulty translate what it says. Still, I read distinctly on the first instrument sent over from America to me, a message that was sent to me by its inventor, Mr. Edison. He said distinctly, "How do you do? What do you think of my phonograph?" Those words were spoken into the instrument in New York, were carried across the Atlantic, and more than a fortnight after they were uttered, I heard and translated them. But the principal purpose to which it was thought that it could be applied, viz.: to dispense with our friends the shorthand writers, is, I am afraid, still very far in the future. It has been proposed to fill libraries with speeches, with sermons, with plays recited by eminent actors, but the instrument has not yet reached that stage when such a thing is probable. It remains an extremely interesting scientific toy, a wonderful novelty. But it is only a chick. It is only three months old, and if it can do what you have heard to-night when three months old, what will it do when three years old? One of the purposes to which it is proposed to be applied is this. This is what Edison says—"I see the President of the American Philological Society the other day, and he had a conversation with a Portuguese who was in the room through the phonograph. He wants one of my improved phonographs to preserve the accents of the Grassiguayed Tecacurua, who are dying out. He did not mean speaks the language fluently and correctly, and he is afraid he will die. You see, one man goes amongst the Indians and represents the pronunciation of their words by English syllables; another represents the same words differently: there is nothing definite. The phonograph will preserve the exact pronunciation, and the President of the Philological Society means to have it shown to posterity this piece of tinfoil.

I do not think I can show you any more of the wonderful performances of this instrument collectively, but we will bring it to a close for your amusement for some time. I am much obliged to you for the attention you have bestowed, and I must say I have felt great pleasure in bringing the phonograph before the British public. I am the inventor of it was kind enough to send me the second instrument that was ever made, and it has been my privilege as well as my great pleasure to bring his wonderful invention before the British public.

The Chairman said he had two duties to perform; one to invite discussion on the paper, which seemed almost impossible, for very few present could have sufficient knowledge of the machine, or the principle upon which it was constructed, to discuss it; and the other, to ask the meeting to return a cordial vote of thanks to Mr. Preece, for the exceedingly able manner in which he had brought the subject before them. If, however, any one should desire to ask for any further information, he was sure Mr. Preece would be happy to answer any

questions which might be put. It was a great privilege for the Society of Arts to receive, as it had done that session, two papers upon such novel and interesting subjects as the telephone and phonograph. If any Dining were wanted to show the appreciation of the Society, and the respect to which it was entitled, it was supplied by the fact that such subjects were brought forward, and held before the public in the manner in which they had been by Professor Hall and Mr. Preece. Great praise was due to the latter gentleman for the quiet, unassuming, and lucid way in which he had treated his subject. It was another step in the knowledge of nature, and in those discoveries in which the present age had been so fruitful.

The vote of thanks having been passed,

Mr. Preece, in returning thanks, remarked that one peculiarity of this instrument seemed to be that it possessed great intensity of sound, and whether it were used in a small room or a large one, it seemed to fill up the whole space. He had used it in rooms twice or three times the size of that, and every person present had heard it as distinctly as they had on that occasion.

ADDITIONAL LECTURES.

EXPLOSIONS IN COAL MINES.

By T. Wyr, F.C.S.

Lecture III.—Delivered Feb. 17th, 1878.

The four forms of safety lamps described in the last lecture are types of a very large number of lamps which have, from time to time, been introduced; each form of lamp has its own advantages, but no lamp is to be found the use of which, under all circumstances, is quite free from danger.

Lamps of the original "Davy" form are the most liable to permit the passage of the flame through the wire gauze.

In the "Stephenson" lamp a danger is apt to arise from the irregularity of the holes in the plate, of which although all sky enters; these holes are drilled by hand, and under these circumstances little accuracy cannot be ensured to the same extent as in the machine-made wire gauze. A "Stephenson" lamp requires to be held in a nearly vertical position.

In the "Clanny" form of lamp the imperfect supply of air is a difficulty, as it is attended with a loss of light. That this is the case is well illustrated by comparing a "Clanny" with a "Museler," in which the former, the two bottle air supply in the "Museler" is coupled with an increased amount of light.

The following comparative experiments, which were made with a view to these features, exhibit the relative photometric value of these four lamps; surrounded by the gauze, or gauze and glass:—

A Sperm Candle burning 120 *grains per hour* = 1 *Oil Lamp.*

Loss or gain in light as surrounding the flame with the upper part of the lamp, per cent.

"Davy"	Naked	= 39
	Complete in 24 hrs.	= 43 loss.
"Stephenson"	Naked	= 36
	Complete in 24 hrs.	= 64 loss.
"Clanny"	Naked	= 42
	Complete in 24 hrs.	= 21 loss.
"Museler"	Naked	= 36
	Complete in 24 hrs.	= 4 gain.

The observations were made by means of a Bunsen photometer, and they need were not many working lamps, but new.

In this table it is seen that, when the naked light is enclosed within the lamp, there is a considerable loss of light in each case, except that of the Museler, and this remarkable difference in this instance must be attributed to the more perfect supply of air in this lamp. Practically, the placing of the glass and gauze round a Museler lamp makes no difference in the amount of light obtained.

Occasionally, for special purposes, shields or reflectors are placed entirely or partially round the lamps on a level with the flame, but their advantage is very doubtful. Before quitting this subject, a form of lamp, which is in extensive use in Scotland, must be mentioned. This lamp is called a gauze lamp, and is of a somewhat primitive construction; it is much larger than the other forms of lamps, the outer case consisting entirely of superposed gauze. This gauze cylinder is about 8 inches high by 3½ in diameter; a lamp with a flat wick is used, and more light is obtained from it than from the ordinary Davy, but its safety is not so great; the considerable space within the lamp forms an element of danger in the event of its being exposed to an explosive atmosphere. This description of lamp was in use at the Blantyre Colliery when the terrible explosion took place last October.

Vegetable oils are mostly used in lamps, but in some cases the rock or mineral oils have been substituted; there is a prejudice against these latter which has prevented their common adoption, although the saving in cost, the cleanliness in use, and the much greater amount of light obtained, are decided advantages; it is probable that these important considerations will eventually lead to their more general use.

All gives more than twice as much light, under the same circumstances, as one of the vegetable character. Some lamps burning the lighter mineral oils are constructed without wicks, a small piece of cotton wool or sponge serving the purpose of a wick for an indefinite length of time. When lamps are used with these oils, care and caution must be exercised in the storage of the material and in the filling of the lamp.

Although the introduction of the Davy lamp marks a very important era in the working of coal mines, it singularly happened that the number of cases largely decreasing the accidents from explosion, those in the immediately succeeding years became greater. The Davy lamp was introduced and adopted in 1815, in the 21 years previous to which the average annual loss of life by explosion was 20, but in the 21 years subsequent to its invention there was an increase, the yearly destruction being 28; this fact, although remarkable, is accounted for by the false notion of absolute security in the use of a Davy lamp which was held at the time, and which led to the immediate sparing up and working of dangerous places which had previously been abandoned.

Dangers Connected with the use of Safety Lamps.

From what has been already said it will be gathered that safety lamps can be by no means implicitly trusted to prevent an explosion; much care is required in their construction and use, as

CHRISTIAN AT WORK

NEW YORK, THURSDAY, MAY 23, 1878.

ALL ABOUT THE PHONOGRAPH.

A Visit to Mr. Edison and What Came of It.

Epicurus—The Value of Speech—Mr. Edison—Experiments—Prose and Poetry—Singing and Whistling—Gray's Elegy—Annabel Lee—Rare Tests—The Phonograph—What it Is—All about It—A Wonderful Thing

BY RANDAL H. BRIGHT.

"DOES any man," inquires Epicurus, in his discourse on the Faculties,—"does any man say that there is no use or excellence in the speaking faculty?" And then he answers his own inquiry by replying, "That would be foolish, impious, ungrateful to God." That was before the days of the printing-press or the telegraph, the telephone or the phonograph. Every year gives increased importance to speech: words uttered by the lips have caused war, brought armies together in the shock of battle, procured peace, made the stories of loves and friendships which will never die till history itself perishes; in brief, speech has made the world what it has been and is from the time when Adam first heard the Lord's voice in Eden till now, when a single speech in Parliament or a single utterance of one man in St. Petersburg may bring together two of the mightiest empires of the world in the conflict of arms. Anything, therefore, which tends to perpetuate speech must have an important effect upon the civilization of the world; and hence it is that the printing-press is regarded, and justly, as an invention which is important next only to that of the alphabet itself. But what place shall be given to our later Phonographic—an instrument which not only records the articulated words of speech, but, as it were, stereotypes them, handing them down to the ages, and not only this, but actually records the distinguishing quality of the voice, so that it can be literally said of one when gone that "he being dead yet speaketh"?

The Phonograph: who has not read about it, heard about it, talked about it, and—shall we not say,—doubted? The writer confesses to having done all these; and so, not having quite so much confidence in any one's eyes and ears as his own, he determined to go and see and hear for himself; and so it was that one pleasant May morning one of the Editors of this journal and a friend, whom we will call the Astronomer—for he has a way of looking at the stars, calculating eclipses and transits, etc.,—got their tickets for Menlo Park, New Jersey—a little hamlet on the line of the Pennsylvania Railway, at perhaps one hundred inhabitants—which they reached about noon, after an hour's ride. "Go right over the hill yonder till you come to a long two-story frame building, covered with lightning-rods and wires, and that's Edison's place." These were the station-master's directions; and following them the building was soon reached. Entering, various philosophical apparatus, electric machines, batteries, telegraph machines, clock works, met caught the eye, while the further end of the building was devoted to a machine-shop, some fifteen lathes—the monotony all highly finished—being run by a compact, lively little lathe en gine. In this shop some fifteen men are employed, making phonographs and telephones, and working away at some of Mr. Edison's inventions—for invention with Mr. Edison is both a business and profession, he having already over two hundred patents at Washington. Ascending the stairs, a young man was noticed sitting by a long table, his hands covered with acid stains, and giving other indications of being one who manipulated the chemicals pretty freely—for there was a laboratory in the building that would have delighted a Liebig or Horsford. Approaching him the Editor inquired for Mr. Edison. "I am Mr. Edison," was the quiet reply, "and happy to see you." Mr. Edison who had been invited beforehand of the proposed visit, and extended an invitation to "come on any day," [illegible] reader] at once sat down to his Phonograph, and placing his lips close to the mouth-piece, and his hand upon the crank of the cylinder, which he turned, repeated in a loud voice: Mary had a little lamb, its fleece was white as snow: And everywhere that Mary went the lamb was sure to go. Jack and Jill went up the hill to get a pail of water; Jack fell down and broke his crown and Jill came tumbling after.

Then reversing the cylinder back to the starting point, he withdrew his lips from the mouth-piece and loosened the crank. In a tone not unlike that of the falsetto, but having all the characteristics of Mr. Edison's voice both as to quality and emphasis, back came the reply clear and distinct: "Mary had a little lamb, its fleece was white as snow; and everywhere that Mary went the lamb was sure to go: Jack and Jill went up the hill to get a pail of water; Jack fell down and broke his crown, and Jill came tumbling after." We had heard that the Phonograph would do such things, but it must be confessed the speech was a surprise. The Astronomer looked as if he had just discovered a planet. Putting on another sheet of foil, Mr. Edison sang in the mouth-piece:

"Who will shed a gentle tear
For a wandering refugee?"

Reversing the cylinder, the Phonograph repeated the inquiry, the melody being rendered as distinctly as the words, "Who will shed a gentle tear for a wandering refugee?" Then came the Editor's opportunity, and applying his lips to the Phonograph he repeated:

The curfew tolls the knell of parting day;
The lowing herd winds slowly o'er the lea,

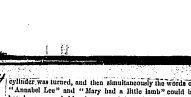
"*Louder, louder if you please,*" interrupted Mr. Edison. So the Editor raised his voice:

The ploughman homeward plods his weary way
And leaves the world to darkness and to me!" Then the Phonograph so unexpectedly repeated Mr. Edison's interpolation, which was spoken away from the instrument, the Editor was taken all aback, and a strange light dawned in the Astronomer's eye. Then came the Astronomer's turn, who repeated four lines of a *verse de société*, which came back with all the peculiarities of his enunciation. Mr. Edison then opening a volume of Poe's poems proceeded to read, interspersed with coughing, laughing, etc.:

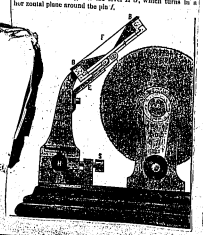
It was ahny and many a year ago ha! ha!
In a kingdom by the sea,
That a—coughmaiden lived whom you may—cough—know
By the—whistle—name of Of an—ahh—Annabel Lee;
And this maiden she lived with no other thought—thought
Than to—ha! ha!—love and be loved by me!

The verse, it need scarcely be said, was repeated verbatim with the coughing, laughing, and whistling, as interpolated. Wonderful as this all was to novices, more wonderful things were to follow. "Do you sing?" inquired Mr. Edison. The Editor confessed he had tried to sing tenor occasionally. "Well, I'll sing the air of 'John Brown's Body' while you sing the tenor." Right lines were sung,—Mr. Edison and the Editor joining their voices in a duet,—the cylinder reversed, started again, and then came out the two voices as clear and distinct as if singing in a choir. Then calling two assistants, Mr. Edison repeated a verse of "Annabel Lee," an assistant at the same time repeating right lines of "Mary had a little lamb," while another turned a little music box which played a waltz. Back to the starting point the

cylinder was turned, and then simultaneously the words of "Annabel Lee" and "Mary had a little lamb" could be heard, accompanied by the music of the waltz! Mr. Edison continued his experiments: when he shouted the Phonograph shouted, laughed when he laughed, coughed when he coughed, and whispered when he whispered, quoted Virgil, spoke German or French as he gave it occasion. And now we come to the question which the reader has doubtless asked a dozen times as he has been reading this article,—How is it all done? That question we will now endeavor to answer. And here let it be said that while the fact that articulation and all the peculiarities of human speech should be recorded and repeated is puzzling beyond degree, the machine itself is a marvel of simplicity:



Edison's Speaking Phonograph—of which the above is a perfect representation—consists of a brass cylinder, *G*, about six inches long and four inches in diameter, turning on a screw-axle which passes through the standards *A* and *B*. On the right end of the axle is the crank, *D*, and on the left the fly-wheel, *E*. The portion of the axle to the right of the cylinder has a screw-thread cut on it which, working in a nut in the standard *A*, causes the cylinder to move to the left as the crank is moved from you,—the direction it is given when speaking. To reverse the cylinder the crank is of course turned toward one, when it moves back to the right. On the surface of the cylinder, running entirely around it, are scored the same grooves as in the thread of the axle, and about fourteen to the inch. *F*—shown in end-half scale in Fig. 2—is the mouthpiece or diaphragm to which the lips are closely applied when speaking. Just below the small hole in the centre of this mouthpiece is a tiny plate of iron only one one-hundredth of an inch thick, which is sensitive to the slightest concussion of air. This plate can be moved toward and from the cylinder by pushing in or pulling out the lever *H D*, which turns in a horizontal plane around the pin *I*.



Underneath this thin iron plate *A* [Fig. 2] are two small pieces of rubber tubing, which lie between the plate and a spring attached at *K*. To the end of this spring is fixed a rounded stylus or steel point, *P*, which bears slightly into the grooves scored on the cylinder, and which are cut much as the threads are cut on a screw. The distance of this point, *P*, from the cylinder is regulated by the set-screw, *S*, and the sliding lever, *H G*, in Fig. 1 as previously stated. Over the iron plate, *A*, is a disk of vulcanite, *B H*, with a hole in its centre. The under side of this disk nearly touches the plate *A*. Its upper surface is cut into a shallow, funnel-shaped cavity, leading to the opening in its centre.

To operate the Phonograph the cylinder is first wrapped around with a sheet of the foil slightly overlapping and gummed at the end. The mouth-piece *F* is then moved close up to the cylinder, till the point *P* bears against the tin foil sufficiently to make a slightly depressed line on the cylinder as it is turned. The cylinder is at this moment placed to the extreme right so that the point pursues the outmost left groove. The mouth is now placed close to the opening in the vulcanite disk, *B H*, and *the metal plate is talked to* while the cylinders revolve, moving uniformly towards the left. The plate, *A*, vibrates to the voice, at the rate of *five hundred vibrations to the second*, more or less according to the "pitch" of the voice. The point, *P*, indents the foil, impressing in it the varying numbers, amplitudes, and durations of those vibrations. If the vibrations given by the voice are those causing simple sounds, and are of a uniform, regular character, continued without intermission, then similar regular, continuous, undulating depressions are made in the foil. If the vibrations are those causing complex and irregular sounds (like those of the voice in speaking) then, similarly, the depressions made in the foil are complex and varying. Thus the talking and inelastic foil receives and *retains* the mechanical impressions of those vibrations with all their minute and subtle characteristics.

Supposing the speech or whatever it is to have been made it now remains to secure from the phonograph *the same vibrations which made their impressions on the foil.* Nothing is simpler yet nothing more wonderful. Pulling away from the cylinder the mouth-piece *F*, with its plate *A* and point *P*, you reverse the cylinder till you have the beginning of the impression back to the point *P*, as it was when you commenced your speech. Now bring the point *P* against the cylinder, so it will rest on the very first indentation which it made. Place in the mouth-piece *F* a large funnel or cone of paper or the to act as a sounding board, and then steadily turn the crank *D*. The stylus or point *P* at once traverses the indentations already made; these cause the point to vibrate precisely as before; it communicates its motions to the iron plate *A* which gives out its vibrations to the air; the Phonograph *talks back precisely what you said to it, and you can hear your own voice repeating your own words.* This is the sum total of what the Phonograph is. Of course much more might be said as to the various experiments which have been made for perfecting this marvellous instrument, but enough is given to afford the reader an intelligent conception of the working of the Phonograph, and if it be asked *what is it good for?*—what endeavor is served by it?—the answer is one which may only be limited by the imagination. The cylinder of Mr. Edison's present machine contains sixteen grooves or threads to the inch. With fifty words to each revolution the present ten-inch cylinder contains 800 words to the inch, or eight thousand to the sheet. Mr. Edison says he can score 1600 threads or grooves to the inch, which would give 8,000 words to the inch, or 60,000 to the entire sheet of foil, equivalent to nearly an *entire issue* of THE CHRISTIAN AT WORK, advertisements and all! With larger cylinders why may not whole volumes be printed on one sheet of foil, those multiplied by stereotyping on copper, so that books can be preserved in this form and by being placed on the Phonograph the entire story be told to the listening ear! In like manner some of the great singers—a Kellogg, Nilsson or Cary may be, we believe will be, induced to sing in the ear of the Phonograph and the electrotyped cylinders be transferred so that we can at pleasure have the actual voices of the gifted daughters of song in our own homes. The Phonograph, too, may dispense with letter writing; for, instead of the usual four page letter to be read in five minutes, you can sit down to your Phonograph, and in half an hour or longer to your friend, take off the foil and mail it or some more durably prepared duplicate to your friend who will put it in his Phonograph and listen to your discourse. Sermons, editorials and lectures, and literary work of all description can also be prepared in this way, and one be enabled to do in half an hour with the Phonograph what the pen might require a day to accomplish. The Phonograph will be invaluable to the lawyer, will *sit away* with the stenographer and save the cost and the trouble of an amanuensis. But it is idle to *speculate* in a field whose horizon is so boundless; but it may be said that the Phonograph will undoubtedly supplement and perfect the telephone and revolutionize—as Mr. Edison claims in an interesting article in the last *North American Review*—the present system of telegraphy. Certainly by connecting the telephone with the Phonograph, the speaker will be enabled to simultaneously transmit and record his own message—and no system of telegraphy does that. It only remains to be said that Mr. Edison is a born inventor. He is furthermore a quiet, retiring, modest gentleman, very young indeed for one who has leaped into enduring fame, yet not leaped, exactly, for he had seen hard times; but courage, pluck, persistence and rare genius have done their work, and he is reaping a reward as deserved as we are glad to know it is substantial. His Carbon-Telephone and Galvanometer which were kindly exhibited and explained by Mr. Edison's accomplished assistant, Mr. Bartlett—are marvels in their way and would require another and more extended an notice which we may hope to give on some future occasion. Mr. Edison told the writer the other day that America had nothing relating to telegraphy to learn from England; but he did not add that it was his own discovery of the quadruplex telegraph which had given America pre-eminence in that field. Mr. Edison's genius is only equalled by his modesty.

POLITICAL TOPICS.

We Dom Pédro: Greeting!

"CAPTAIN" COLMAN SENDS AN ADVANCE REPORT OF MR. JOHN MARSH'S PHONOGRAPHIC SERMON.

To the Editors of the Evening Post:

On the arrival at the steamship Bay of Rio de Janeiro at her destined port the phonograph which Mr. Roach had loaded with 10's' congratulatory message will be duly forwarded to the palace of St. Christoph. We may imagine the machine to have been placed in working order for the entertainment of the imperial family and the assembled guests.

"Your Imperial Majesty," the instrument begins, "I congratulate you on the success of an American enterprise. I have built an American ship of American iron, with American workmen on an American shore, and launched her into American waters. She is owned by American citizens and will be sailed by American sailors. She won't carry any but American passengers, nor any goods but American goods. If you want to write a letter to send by her it must be in the American language. Not a drop of whiskey will you get aboard of her but American, and the wine will be the pure juice of the American grape. You see, your Majesty, I'm a protectionist. I believe that every true citizen of yours ought to protect one man, and that's me. I've blarneyed and bulldozed Congress for years, and I've made 'em believe that they ought to subsidize only American built ships for the benefit of American shipbuilders, just as you only subsidize Brazilian built ships—eh, dear, I forgot! when you get a word into the confounded phonograph you can't gainsay it; and now here's I got my celebrity from Brazil?"

At this point the instrument began to wheeze and cough and contrived in such an extraordinary manner that all attempts to complete it as meaning were ineffectual.

J. C.

New York, May 12, 1879.

N. Y. Clubhouse May 25

LYDON'S PHONOGRAPH will be exhibited in Mechanic's Institute, Baltimore, commencing May 27.

MADDI LAVERNE and stereopticon at 20 opera, and views illustrating every subject for 25 cents. Admission to the theatre included with the lecture. Ask for circulars.

ROBERT HILLES is to give entertainments at Bellevue, Ohio, on Monday, New Haven 28, Hartford 29, Meriden 30, Ansonia 31.

HUNSICKER & HUNSICKER'S BALLOON SHOW exhibited in Bucks Co., Pa., on Saturday, Kennett 11, Abingdon 12, Penn Square 13, Lancaster 14, and Carriage 15. They close in Maryland June 1, and will be at Newark, Del., Kansas, Arkansas and Texas.

SOLAR TANNHÄLLA is to commence a concert-season at Steinway Hall, New York, on Sunday afternoon, June 4. Signor Tannhäuser of the 5th Cavalry Circuit and Philadelphia Literary Society, will be present, and will be invited to be heralded in Broadway St., Bridport.—The finest Social Society of the day.

PROFESSOR ——, Investigationist, Mass., can be engaged for a limited time until Sept. 15. It will be a great literary treat. Address, Box 1.

THE NEW NATIONAL THEATRE, Philadelphia, is offered for sale, or it can be leased thereof. Apply to Messrs. Smith, Brown & Co., whose address may be easily found.

THE HIBBON SEVARIN PHONOGRAPH was exhibited in Cincinnati, Ohio, Toronto, Miami, the past week will be continued [illegible] next week.

Boston
EVENING TRANSCRIPT
THURSDAY, MAY 25, 1876.

THE MORNING'S NEWS.

EDISON'S LABORATORY.

A DAY AT MENLO PARK WITH THE GREAT INVENTOR—THE CHIEF PHONOGRAPH—THE AUTOPHONE, PHONOMOTOR AND OTHER INVENTIONS—HOUSEHOLD MUSIC.

By the courtesy of the management of the phonograph exhibition at Horticultural Hall, represented by Mr. Lyon, the Boston press passed yesterday at Menlo Park, New Jersey, with Mr. Thomas A. Edison, the young man who chose leisure through the telescope pointed toward the towers of the Brooklyn Bridge, dimly seen in the horizon. Through the glass the wire cables were clearly discernible. But Mr. Edison is now returning across the field with the particular object of our visit.

THE PHONOGRAPH.

They pause by the telegraph pole, and in its shade, for it is all blaze elsewhere over the sandy soil, Mr. Edison lights a cigar. He is an inventor, and consequently not a dilettante, believes in no narrow ideal, and declares that Yankees get their many inventions because they have other people's ideas to make kinds of fools of. He approaches with an easy gait, and above his head we hear the voice of his companion, for, as he walks on, the great inventor in the field of acoustics is slightly deaf. While the party is being introduced we will scan him more closely.

He is in form athletic, graceful and slightly above medium height. A more pleasing combination of voice and eye are not often encountered. The photographs and periodical portraits may be considered good and at least caricatures, for they represent him as a cupcordial, listless and consequential. The eye is dark, smooth nevertheless and is bagged and pale, and the face coarse and almost straight hair radiates from a head with not his large head, rotundities, eye and mouth; that his thin eye looks weary with night work and artificial sleep. But as kindly and youthful an expression, as frank and clear a countenance, and as noble and withal graceful a head are rarely met with. When in conversation his face and eyes light up with a peculiar glow of earnestness that stamps him as no common man.

Apologizing for not having arisen sooner, with the remark that he expected to at ten o'clock, he seated himself in a armchair before

THE PHONOGRAPH,

the first practical one ever made, and adjusted a

The cylinder had not been evenly cut, and when first placed in position would not work, not being properly balanced. The rear room is the machine shop, containing at least a dozen lathes, dies and other machines. About fifteen men are employed here from eight o'clock in the morning until eleven in the evening, but nothing is made except for experimental purposes. The room above is the laboratory proper. As we enter, a card with an order in the top, square hand of Mr. Edison. "No admittance except on business. This rule must and shall be enforced," with the "must" and "shall" doubly underscored, looks us in the face.

Nevertheless, we have been invited, and therefore enter. In the large hall everything appears in place. The wall is lined with more than 200 books. Every chemical that is known is here, said an assistant; everything in the botanical line also—roots, herbs and seeds. Indeed, we found not only everything, from "dragons' blood" (a vegetable substance) and Brazil wood to Iceland moss and gold wire, but preserved snakes, and, in a case in a corner, watches, razors, and many common and uncommon mechanical contrivances; conical paper funnels, six feet high, a big galvanic battery, the sound and music box.

Of course, the whole laboratory fixtures and experimental apparatus, electrical batteries, instruments, an air pump, translators, [illegible] pressure, etc., were present. But an induction coil, which is in disuetor and eighteen inches long, was a novelty. It is a recent addition, cost originally $100, and is capable of flashing a spark ten inches long—quite a scrawn of lightning.

The patent-office model of the phonograph, a miniature machine about three inches in length, and the first experimental phonograph, a clumsy instrument with cylindrical box drums upon each side—rests recently discovered and waiting to suit its—was examined. Beside the first practical machine, which we have at home, Mr. Edison exchanges about calling by a well-handled copy of the poems of Edgar A. Poe, very effective by Mr. Edison's favorite.

It opened readily to the "Shonest to Science," one of Poe's youthful poems, beginning—

"Science! true daughter of old time thou art!
Who alterest all things with thy peering eyes."

We had no need to read further, Passing to the phrase, those who chose looked through the telescope pointed toward the towers of the Brooklyn Bridge, dimly seen in the horizon. Through the glass the wire cables were clearly discernible. But Mr. Edison is now returning across the field with the particular object of our visit,

THE PHONOGRAPH.

They pause by the telegraph pole, and in its shade, for it is all blaze elsewhere over the sandy soil, Mr. Edison lights a cigar. He is an inventor, and consequently not a dilettante, believes in no narrow ideal, and declares that Yankees get their many inventions because they have other people's ideas to make kinds of fools of. He approaches with an easy gait, and above his head we hear the voice of his companion, for, as he walks on, the great inventor in the field of acoustics is slightly deaf. While the party is being introduced we will scan him more closely.

He is in form athletic, graceful and slightly above medium height. A more pleasing combination of voice and eye are not often encountered. The photographs and periodical portraits may be considered good and at least caricatures, for they represent him as a cupcordial, listless and consequential. The eye is dark, smooth nevertheless and is bagged and pale, and the face coarse and almost straight hair radiates from a head with not his large head, rotundities, eye and mouth; that his thin eye looks weary with night work and artificial sleep. But as kindly and youthful an expression, as frank and clear a countenance, and as noble and withal graceful a head are rarely met with. When in conversation his face and eyes light up with a peculiar glow of earnestness that stamps him as no common man.

Apologizing for not having arisen sooner, with the remark that he expected to at ten o'clock, he seated himself in a armchair before

THE PHONOGRAPH,

the first practical one ever made, and adjusted a new sheet of tinfoil upon the cylinder. The phonograph in motion must be familiar to all. The Transcript has already published an accurate description of it, and most of its readers have doubtless seen the instrument. The cylinder of the machine at which Mr. Edison is seated is of brass, and is received by steam power sent up from the starting below. The rod, therefore, has a small balance wheel. The mouthpiece or [illegible] is of iron, and that attached to the later machine is simply a plate capable of receiving a small diaphragm, sound vibrators, with a short needle or point glued to its centre and resting in the groove of the tinfoil sheet. Edison lets on the power and again into the machine, "The dying soldier faltered as he took that [illegible]'s hand, and he said, 'I never more shall see my own, my native land. Take a message and a token to some distant friends of mine, for I was born at Hoppor, fair Bingen on the Rhine.' I am singing to this machine." Returning the cylinder to its first position, he placed a paper funnel at the speaking end, and then too wide a dispersement of sound, adjusting the cylinder again reproduced his speech with a remarkable variation in tone and distinctly audible over several feet distant. This is the work of the invention with which the public is already familiar. Now over the same piece of tinfoil he whistled "Auld Lang Syne," and reproduced the poetry and whistling together, yet eachas distinct as though one person were whistling while another spoke. Then over the same sheet he whistled, sang, and reproduced, as before, the three pieces. Again and for the fourth time he went over the foil, this time calling in base tones and talking, "Rub-a-dub-dub, three men in a tub, the butcher, the baker, the candlestick maker, all turned out of bed to eat pease porridge hot, three, four, five, six, seven, nine, ten." The phonograph operates now beyond "dingen on the Rhine," whistled, cackled, and called "Rub-a-dub," all together, and with nearly as much distinctness as four different voices speaking at the same time could be done it. Then the whole was given in reverse order, beginning with the whistling, through somewhat shortened, was distinct. Another piece, "Yankee Doodle" was whistled and given backward, producing a different tune. Mr. Edison has not yet succeeded in giving a consistence tone to the phonograph, but is confident, during the afternoon, one of his assistants mildly called in a "good day" and during the cylinder backward was answered in a shockingly profane manner.

THE PHONOMOTOR.

This property of repeating sounds backward is considered a great acoustic value in the phonograph. "John Brown had a little Indian, John Brown had a little Indian, John Brown had a little Indian—the Indian died, John Brown had a little Indian—the Indian died, and he sings," was sung as fast as the words could be read, and then in reverse direction and a note was lost. Attempting to reprise the song of "Annie Laurie" the cylinder stopped and how the work. Installed a screwdriver readjusted the "arm" and the "Wandering Refugee" was sung in a fast bass waltz. Then, over the same foil, Mr. Edison sang it again in a different tone, and the phonograph repeating both parts, treated the company to a duet. "There," said Mr. Edison, "it is it's every one that can

SING A DUET ALONE."

Then upon a clean sheet Mr. Edison he sang and whistled, and another duet was given, though there was a want of harmony, for this reason, and is given a musical property in the instrument—As the sound waves are received by the diaphragm and pushed the needle point to the right location, and this is heard through the same vibrating plate that he is speaking upon. Thus the same plate is passing vibrations for registration upon the foil while it is receiving, or speaking, from the same foil the first record. In this instance, the whistling being so much sharper, produced the ear of the whistler hearing perfectly the foil, and thus unison or harmony was not obtained.

Mr. Johnson laughed into the instrument to [illegible] as to drive the stylus through the tinfoil, performating it for several inches. Nevertheless it returned the laugh. It also reproduced Mr. Edison's coughing, blowing and blasting. Mr. Charles Batchelor, the inventor's principal assistant, was served. The diaphragm was capped

with a double mouthpiece, and placing their heads close together, Mr. Edison and Mr. Batchelor sang "John Brown's body lies a-mouldering in the ground," etc. No poorer tones or clearer harmony could be asked in a concert room than that with which the phonograph re-sang the duet. Excepting the mouthpiece, it were a musical treat to hear the singing. Another time keep away this piece of foil as a rare [illegible].

The little wonder—for astonishment was re newed at each different performance—was then made to speak in German, French and Latin. "We get the best results in Latin," said Mr. Edison, "and the poorest in English." Then he attached the foil and the diaphragm, which he called "oscillating the record." The voice in the reproduction was not so distinct, but each word could be understood. "I make it talk inaness, this way," said Mr. Edison.

THE PHONOTYPE.

"Blow for once a word received on the foil?" "Why not, sir," was Mr. Phonograph. There, that extends once round the foil, and there are 600 vibrations for that word."

Then Mr. Edison spoke through the funnel—about a foot in length; then off a foot from the funnel, or two feet from the instrument. The repetitions were clear. "With a pasteboard diaphragm," said he, "which is much more sensitive than the brass," and took from a drawer a piece of pasteboard and an India inst it twelve feet. I think I shall use it hereafter in place of the 'regular' machine." Turning the crank by hand he spoke into it again, and then went back to the foil that the sound became a mixture instead of articulate speech.

"We had two machines together here the other day," said he, "and connecting the diaphragms by a long rubber tube, ground of three or more miles, so that the words were whistled through the tube and reproduced at the other end. There was considerable speech from the second machine, tearing it that two rubber tubes were needed to two revolutions. Then the same were connected with three half a revolution. That was at the rate of forty-five words a revolution; there are sixteen threads to an inch, and the diameter is eight inches.

This calculation allowed for 2700 words upon one plate of foil, 1,782 inches, or about three cubic feet. Multiplying by ten, "I can do it in a day now," said he, "I will take fifteen hundred threads to an inch and double the speed, and I can record twelve times as many words—about 32,000. That is equal to the matter of a 250 page book."

THE AUTOPHONE.

When Mr. Edison was showing some results of his investigations in Philadelphia, some one in the crowd remarked, "Why don't you invent a machine to talk a fish through a hose?" It brought a sarcastic and replied, "I guess I can." He returned home and constructed a small phonomotor which the company now turned to look [illegible] and which comes from a battery plate with a bar at each connecting the centre of it with the centre of the other plate. Over the plate moved the cabinet wheel and another wheels attached upon the same shaft. Several of the wheels are cut with a screw, and each has a wheel whistling at a rapid rate. Neither blowing nor any other force except the human voice would move it.

THE MOTOPHONE,

or second engine, was a curious musical instrument. It was based on the same principle as the former. A spiral was cut on the face of a brass [illegible] the top end of a bench. To the centre of its face was attached a [illegible] upon which was placed a [illegible] and to the other end of about fifteen pounds upon the rim of a small wheel. Over the wheel and the spirally-prepared paper was passed from a spool. A current of electricity was given to the wheel. Mr. Batchelor, below, sang several airs through a telephone, and they were repeated by the harp—the musical tones only. At the same time Mr. Edison revolved the small wheel and gradually drew out the electrically-prepared paper, which was received by the spool, and was acted by the current of electricity increasing and decreasing the friction upon the strip of paper. When there was no current passing, the paper was moved with difficulty, and consequently, as it was drawn out, it slightly drew out into the air attached to the sounding-board. A current immediately reduced the friction, and the [illegible]

springback, shuttling into sounding-board. The machine is capable of 30,000 vibrations a second. It should be remembered that the Edison telephone is merely the increasing and decreasing of the force of an electric current by sound vibrations. Why electricity disinclined to follow the vibrations of sound. The solution on the paper was bluestone and water, which acted the best, but he had tried 20,000 different kinds of chemical combinations. Some of these increased the friction against the paper. Only salts were found to work well, and the more alkaline the better. The same principle was shown in other electrical apparatus. For the practical purposes,

THE SPEAKING PHONOGRAPH.

"What is this speaking machine?" said one of the party, pointing to a horizontal cylinder, a bent bar of iron fore and aft of it, and a mouth-piece. "It is a perfected wireless telegraph," said Mr. Edison, "and a harmonic engine," said the inventor, with a fatherly smile, "it is really a large tuning fork. I can utilize its vibrations by connecting it with a battery of four cells so as to make it pump three barrels of water, three' electric lungs, twenty-four hours. I mean to apply it some day to the pumping of water for gentlemen's country residences. I can make it run at one of three rates a day—at one of four notations." He set the large bar into vibration by means of connecting the circuit. It was then an electromagnetic motor of double action, and of about the force of a man's arm. The oscillations were almost at sight of an inch in breadth, and they caused and closed the electric current in unison. The vibrations, in this case available as to be called oscillations, were at the rate of thirty-five a second.

Mr. Edison declared he could make it drive a sewing machine with the quickest possible means, or rather he was setting to get out of order, the magnet opening and closing the electric circuit. But he said he would be obliged to have two sewing machines—one, if accident to the other, to be kept in steam power, so as to preserve the harmony of vibrations. The machine requiring greater power were attached to one end than to the other, the result would be the destruction of vibrations in proportion to the inconvenience of the powers, just as in a musical instrument the harmony is destroyed if the sets of keys are not evenly weighted. For the pumping machine the pumps might themselves be the tuning forks. Edison said that theoretically he got nine-tenths of the power of the battery with this machine. All other machines get but one-tenth of the possible power of the battery, theoretically speaking.

Mr. Edison now instanced his visitors with a practical application of one of his late inventions, the electric pen. This is a pen which, even if quite unconnected over the paper, prints a line by means of a needle moved rapidly up and down in the pen connected with an electrical motor. From this stencil-paper sheets are taken by the common printing process. The inventor's autograph and a picture framed from an illuminated wreath, all done quickly before our eyes, were handed to each one of the party.

THE EDISON TELEPHONE.

was next exhibited and explained with the utmost freedom. It is entirely different in principle to the Bell telephone. Both inventions worked on the same lines on different principles, and precisely. Bell's telephone really makes simultaneous magnet or electrical impulses strike a permanent magnet, and the permanent magnet, and the disturbances of the magnetism by means of extra force. Edison merely allows it to vary in regular—increase or diminish—the force of a current already existing. This is done by means of placing a disk of prosaic carbon, about the size of a dime, between two platinum disks, behind a diaphragm or vibrating, plate, and the pressure of the waves of the voice concentricity, and producing the same compression, reproducing the sound. The carbon disk-plates was spoken through, the speaker standing six feet from the plate. According to the inventor's explanation, it is conveyed that the telephone will reproduce a sound giving but six times more force than the Bell telephone. Mr. Edison showed other apparatus utilizing the sensitiveness of carbon to heat and pressure. Attaching a battery to a galvanometer he pressed the fingerpoint with his finger and registered several degrees of pressure, raising the needle from twelve, increasing the weight of the plate on the carbon disk, to fifty-five. Mr. Edison started experiments in this direction in 1875. In his first telephones he used rubber, but the heat of the voice sensitive was the carbon, made it necessary to substitute iron, and then he used a handle altogether. Steam was found to be more sensitive than iron; thin iron plates will be used in the photograph-harmonic of brass. The thermopile is a usual instrument for measuring heat, and Mr. Edison is now research as sensitive as the carbon. With it and

THE HEAT OF A STAR

of the first magnitude, he could detect an and close a telegraphic circuit. Once he listened to the Mary once playing on a piano and also explained, which, though they did not weary the writer, might weary the reader.

THE TELEPHONOSCOPE,

to do for the ear what the telescope does for the eye, and upon somewhat similar principles—the vibrating waves of sound for the waves of heat, was explained. With them—the receiver and transmitter—he said he would be able to see—instantaneously—pictures that have been carried "on a rifle. The scene is shot out of a bore found like a bullet from a rifle barrel, and must be almost correctly to produce an effect. Mr. Edison pointed to a tree, at the end of a mile distant, and said he had heard the click of a watch over water on his telephonoscope wireless.

After a pleasant visit to the Edison family, the party left for the depot, expressing their appreciation to Mr. Edison in the heartiest manner and with his many friends here as soon as he returns from Europe. Mr. Edison will be accompanied by his children, Dr. Ludwig, he said, he could be glad to.

Thomas Archer is the name of the boy, the manager of Mr. Edison's two magnets. Edison, in this city, for the pleasure and instruction of the reporters mentioned in the Herald.

Boston Daily Globe.

FRIDAY, MAY 24, 1878.

A VISIT TO EDISON.

How the Greatest Inventor Lives at Menlo Park.

Other Art Works and Cares.

On Tuesday evening last the representatives of the Boston press, through, the courtesy of Mr. William Mitchell, manager of the Edison phonograph exhibition at Horticultural Hall, started on a visit to Menlo Park, New Jersey, twenty-four miles from New York, the home of Thomas Alva Edison, whom the Hall Telephone Company, of Boston, have the honor to represent in this section. The party numbered about two dozen in all, the ages, for the most part, of the editorial fraternity, but there were also present Mr. W. H. Forbes and G. Johnson of New York, the business manager of the Phonograph Company, Mr. Mitchell, Mr. Edison's agent, Mr. Batchelor, and several Mr. Edison's personal friends, including Mr. Batchelor, Mr. Edison's personal friends, including agreeable. On Wednesday the assembly met at the Hall, and at 10 o'clock the party started on a special car for Menlo Park, which was reached at 12:30 o'clock. Mr. Edison's residence, laboratory, and electrical manufactory are all within a stone's throw of each other, and the whole establishment is surrounded by a high fence, through which the photograph was put in operation, and the party were shown the wonderful results being attained. The phonograph was then put in operation, and the party were shown the wonderful results being attained. The phonograph was then put in operation, and the party were shown the wonderful results being attained. The phonograph was then

of wealthy, farmers. In the immediate vicinity of the station are several quite extensive dwelling-houses, forming the village proper. One of these houses is the settlement's store. It is two stories in height, painted red, and in front has a wide piazza, extending to the platform. Directly opposite the station, at the foot of which is the railroad station. It is a wooden building, about 100 feet long by 40 wide, and two stories high. The entrance is at the end which is flanked with several large windows. Over the entrance is a modest little sign of the appearance of being a watchman. On entering the building we were informed that Mr. Edison, after receiving a call there, and saying, 'I can't work now, it's 3 A. M., had gone home to obtain a little sleep. Mr. Johnson went to call him, and meanwhile we turned ourselves in an examination of the premises. On the right of the entrance is a private office, containing nothing of particular interest except a blank book and a letter-press. The latter bears the inscription, 'No. 101,' 'Laboratory Stock,' 'T. A. Edison, Menlo Park, N. J.' We suggested that the inventor's address, Mr. The next apartment entered consists about two-thirds of the first floor, and among the contents were cases containing numerous kinds of telegraphic keys, Morse sounders, galvanometers, a thermo-pile, self-clocks, and other articles connected with electrical or mechanical science. Two brick piers afforded support to the ceiling, from down upon a solid bench, and among the more curious articles was a pneumograph in process of construction. It consisted of a glass, a weight, and clock-work carrying the cylinder around, and a receiving pneumon with cardboard tube representing the nostrils. Against the apartment is the stop, where six or eight men are at work under Mr. Edison's direction. A small engine supplies power for the operation of the various machines which are in constant use beneath the floor. These machines are of the most first quality, as are the many tools that are used, and it is evident that those which seem at least too delicate to come in contact with the metals which they cut to those which are used for the most rough work are of the best kind. The workmen, who are mostly young, appear to enjoy their labors very much, and while they appear to have a commendably easy time are quick to understand and execute Mr. Edison's orders. Returning to Edison's private room, we found a gigantic safe in front of which the upper part of the building is used as a fire-proof room, occupying its entire floor. It presents a strange appearance at first sight. Its walls are hexagonal, and the walls are lined with shelves containing chemicals, each plainly labeled. In all directions, from the floor, wires hanging from the ceiling, the ends of to which instruments stands from one direction or another. Mr. Edison's desk is very torn by machines or parts of machines, some familiar and some novel. Only two or three persons were in the room when we entered, and each had access to work in hand. Questions asked of any of them elicit courteous replies, and any remark complimentary to Edison is sure to meet with a hearty indorsement on their part. Mr. Edison, who was very much occupied by all the workmen, was not able to judge by a moment of a few interviews, but we proposed to glance the name of the place from Menlo Park to Edisonville in his honor. In the laboratory, members of our party did not see any interesting in regard to keeping their desks off the articles on the floor and tables. Leading into the office. Even a small pipe organ that stood in one corner with a Moody and Sankey tune book on its desk and a few of the most carefully inclined to indulge in sacred music. There was nothing in the surroundings which said that would make inconvenient business operations. So a large lounge, one call, three chairs, a desk, a table, pen, ink, mouse, phone or medical house, the invention of Mr. Edison, the pneumograph itself, and a few other articles completed with. The floor is quite clean in appearance and admirably lighted, and there is no reason why it does a favorable opinion of the room before he entered. After looking the upper floor before he retired, we went down to the basement, where the boiler, engine, &c., are all in one compartment, and near this is a large wire cable to the car-house, which is to look over the cable to the car-house, which is now building between New York and Brooklyn.

MR. EDISON.

It was not yet 10 o'clock, when, with a quick step, Mr. Edison came in and took a seat at his desk. After meeting the building, we received by all of the party with a consideration of respect, but was by no means reserved, but was in consultation upon, and having greeted each of us in turn proceeded to business. He table on which he placed the phonograph which he now, and which is run by pulleys connected with the machine in the room beneath. The movement of a lever to the right or left gives the cylinder of the instrument a forward or backward movement, and the ordinary motion of the machinery gives smoother effects than the somewhat irregular motion secured by turning a crank by hand. While Mr. Edison is preparing a sheet of the foil to place upon the cylinder we will take a look at him. He is a hard man to describe, and on description yet stress of aim seems exactly correct. He looks young and yet old—years and yet fresh. His face is full of lines, and yet is remarkably free from them. A round head, a high shaped head is that features somewhat scarcely shock of hair, well sprinkled with gray, which projects over, but does not overhang, a fine shaped forehead, that bears several well defined though not deep lines. His countenance is open, his gray eyes are bright, his nose and mouth are well shaped, and he is in face very far from being a beauty man. Close shaven, his flesh is pale and unhealthy in appearance. When he is contemplating he wears a thoroughly serious look, and as he speaks his countenance lights up with animation. His voice is not what is one of weight or of pleasantry. In light he is about 5 feet 7 inches, and excepting a very slight stoop of the shoulders is of good figure and is fairly hale. He is not so-and' as has been described, and it is not a fact that he has never heard the voice of his own invention. He is very hard of hearing, but by placing his ear close to the sounder of the telephone he hears readily, and is very quick to detect false tone or false cause. His voice is soft and pleasant, and he is something of a singer. With a very retentive memory for tunes, he can remember a song after to repeat many pieces from memory, and in doing so delivers the lines with good taste and expression. He has been described as being careless and slouchy in his dress, but the Station party found this description scarcely justified. There was little of carelessness in straight-on, but there was no evidence of elegance. With Mr. Edison's previous history the public is already more or less familiar. He was born at Milan, Ohio, Feb. 11, 1811. His ancestors never came to this country in 1730. The Edisons are a Dutch family. Mr. Edison's father, who survives, lived to be 82 years old, and his grandfather lived to be 103. Mr. Edison's father is still living at the age of 76, hale and hearty, and visiting his son at the other day across. His is a stout footstep. Edison's mother was a Miss Elliott, and was a native of Canada, and was an Scotch descent. Edison's mother died when her son was almost more than two months in age. Mr. Edison's boyhood was passed in Michigan, Indiana, and well settled, and traveled extensively and across. His early years were spent as a newsboy, as train boy, typesetter of a newspaper, editor, newspaper publisher, telegraph operator and inventor. He was married in 1871, and has three children by his present wife. His children are all young, but are particularly fond of their father becoming a telegraph operator he has been a telegraph operator for many years. He has, however, seen to enable him to devote himself entirely to duties or appear more efficient than he really was. He is a thorough master of his profession, and has never taken the first rank in his chosen field. Questions are asked him in the test him best and understand the answers given. Mr. Edison is a believer in the theory that Edison knows to work for his own benefit, and among them are the electric pen and the telephone, the former of which has been in operation for about five years.

THE PHONOGRAPH.

We bid Mr. Edison more necessary ago, preparing the tin-foil to place on the cylinder of his phonograph. It is a very valuable tool, some of our readers may be not aware of the construction of the instrument. It consists of a metallic cylinder, which is covered with tin-foil, and which is run by a crank. Around it runs tool to form a screw-thread. The metallic being very close to each other. The cylinder is covered by a sheet, which by means of a lever can be brought into correspondence with the spiral groove carrying the tin-foil. The sheet is pierced with holes, and on one side of the other. To the sheet is fastened either a mouth or a puller. On the last upon which the cylinder is placed a diaphragm, and to the center of it is an arm which carries a needle point. This arm, moreover, so that the needle-point can be brought in contact with the tin-foil. The mouth-piece is then a disk of thin sheet-iron, which is taken in diameter, on the under side of which is cemented a small piece of hard rubber. Each of the needle-points on the end opposite to the mouth-piece is a small piece of hard rubber, to which is cemented a piece of tin foil is placed on the cylinder, the mouthpiece a few inches from the mouth, and the needle-point on the tin-foil opposite a groove in the foil. The cylinder is made into the mouthpiece the vibrations of the air are communicated to the diaphragm. When these are brought again under the cylinder they reproduce the vibrations of the disk by which they were originally produced, and in reaction on the sounds, articulation or inflection of voice, which, having once been a mere memory, are now a fact. Such is the theory. Mr. Edison reduced it almost applied a little tin-foil to one of the caps, and drawing the steel

assembly across the barrel, pressed the mouthpiece and drew close and as secured it. The examiner then handed it to notice. Edison, placing his mouth to the mouthpiece, recited a verse from 'Hamlet,' as the Editor was then afterward reciting very distinctly for the phonograph. Mr. Edison then set the machine in motion, and all saw the lever move. Turning the cylinder back the operator next attached a 'Yankee Doodle' to the mouth-piece, and as the machine moved the familiar air was heard. The new notes of Indianolive time in three slow music. The result was what the new, and the phonograph of the future all that was claimed for it. Mr. Edison then

BOSTON POST.

FRIDAY MORNING, MAY 24, 1878.

EDISON AT HOME.

A Boston Delegation Visit the Father of the Phonograph—The Wonders of His Workshop.

Through the courtesy of Mr William Mollston of the phonograph management now conducting the exhibition at the International Hall, half a dozen representatives of the Boston press were taken in New York Tuesday night, and on the following day, they proceeded twenty-five miles into New Jersey—Menlo Park, where Mr. Thomas A. Edison maintains his workshop. Mr. Edward H. Johnson, the General Agent of the Phonograph Company, accompanied the party from New York.

The laboratory used by Mr Edison is a narrow, two-story wooden building about 100 feet long. About a dozen men are steadily employed here, but only as experimental work. The building is crowded with machines and the most interesting patents and inventions.

Long before we and Pan, his favorite instrument, Mr. Edison received the party with great cordiality, and supplied them all by his lack of resemblance to the popular idea of a scientific man. He is of medium size, with a smooth, healthy face. He is of medium years, four, and with an evenness of temper which is rarely disturbed. He wears a full beard, but not his hair. He gave us the impression of great vigor, and his every movement was that of a man of decision. He never kept us waiting a moment for his answers, and he never answered a question with "I don't know." Well a scientist of a discoverer of all facts, and his manner would repel rest at once. He was perfectly willing to show us all that he knew, and he knew almost everything. He received us in a large, lasting room and soon he could not a half hour, and we were then ushered into the workshop in the rear building. Here the whole place of the members of the party drove to be confined, much greater would be required in relating on the phenomena of the trip, due to the kindness of their host; but as the public cannot be supposed to be interested in these personal matters, it must suffice to say that every attention was rendered which a thoughtful courtesy could suggest to a host. Dinner was at last the coolest and enjoyable of the season, and three were seconded by the attendance of a number of the ladies of the family.

The party was peculiarly honored, too, by the earliest attention given by Mr. Edison himself, devoting the necessary absorption in his varied scientific experiments. He had been at all the pains might expect, creating a the new phonograph machine which is to be exhibited at the Paris Exposition, and the arrival of the guests being earlier than he had expected he was not fully prepared for them. His assistants, however, all of whom are men of the highest order of intelligence, had been instructed by his New York manager, Mr. E. H. Johnson, who had visited the party at New York. The whole ingenuity of which his country at the laboratory at Menlo Park was brought into play to make the visit interesting, and the success of the endeavor of his assistants it need not be said that the party left Menlo Park with a most high appreciation of the hospitality of the country could have received. And to describe, even briefly, the many new inventions which were explained to us by Mr. Edison's assistants would require a book of many volumes. Suffice it to say that we saw the phonograph in its latest and most perfected form, and that we saw the latest and most perfected form, and that we saw the latest and most perfected form, and that we saw the

fair-sized pipe organ and a small elastic bow."

Of course, the usual laboratory fixtures and experimental apparatus, microscopes, lens measurements, an air pump, insulators, spark generators, etc., were present. Not an induction coil, a foot in diameter and eighteen inches long, was a novelty. It is a recent addition, cost originally $500, and is capable of flashing a spark ten inches long—quite a streak of lightning.

The patent-office model of the phonograph, a cylinder covered with tinfoil, some inches in length, and the first experimental phonograph, a stubby instrument with cylindrical brass cylinder and mica sides—one is not to be sound and another to emit it—was examined. Beside the first practical machine, the one at which Mr. Edison experiments almost daily, lay a well-handled copy of the poems of Edgar A. Poe, though Longfellow is Mr. Edison's favorite.

It opened readily to the "Sonnet to Science," one of Poe's practical poems, beginning—

"Science! true daughter of old Time thou art!
Who alterest all things with thy peering eyes."

We had an need to read further. Nearby to the piano, those who chose looked through the telescope pointed toward the towers of the city, upon Bridge, down Nassau, and across the water. Through the glass the wire cables were clearly discernible.

But Mr. Edison is now returning above the fold with the particular object of our visit,

THOMAS ALVA SPEAKS.

They pause by the telegraph pole, and in its shelter, for the air blows smartly over the hill, Mr. Edison lights a cigar. He is in a boisterous humor as well as his dialect, for there is no narrow diet, and declares that Yankees get their name from an Indian tribe that subsisted chiefly on pie by eating many kinds of food. He approaches with an easy gait, and shows the wind we bear the voice of his companion, for, as is well known, he is somewhat deaf, but in the field of acoustics is slightly past. Indeed the party is being interdicted we will not have overheard.

He is in force almost, and slightly above medium height. A genial, prosperous appearance, voice and air are often observed. The photographs and periodical portraits do not do him justice, for they are not at all prepossessing, for they represent him as ungraceful, listless and concentrated. "I'm true Mr. smooch nevertheless face is haggard and rude, and his coarse and almost repulsive features suggest a canine all over his large head, particularly from a canine all over his blue eye looks wonderfully light work and intellectuality. But as kindly and youthful an expression, as frank and clear a countenance, and as noble and refined a head never was met with. When in conversation his eye lights up with a peculiar glow of earnestness that stamps him as no common man.

The phonograph not having arisen sooner, with the caveats that he expected us at ten o'clock, he seized upon it as a particular before

THE PHONOGRAPH,

the first practical one ever made, and adjusted a new sheet of tinfoil upon the cylinder. The phonograph in outline rest in familiar in all the telegraph that has already published an accurate description of it, and most of its readers have doubtless seen it in operation. The cylinder of the machine, as Mr. Edison is seated is of brass, and is revolved by hand power sent up from the shifting below. The cylinder, therefore, has a small balance wheel. The mouth piece or tube pasaes in like those attached to the later machines—simply a plate capable of receiving and transmitting sound vibrations, with a short nozzle or spike glued to its centre and running in the grove of the cylinder. Mr. Edison then turns the power and spoke into the machine, "The dying Indian suffered as he took his comrade's hand, and he uttered," it never more shall see my own, my native land," as a message sent a token to some distant friends or relatives, for I was born at Niagara, fair Niagara on the Hudson, in very borne the morning." Returning the cylinder to its first position, he placed a paper thin diaphragm over it to prevent too wide a dispersion of the sound, and turning the cylinder again reproduced his words without a noticeable variation in tone and distinctly audible several feet distant. Then, to the work of the invention with which the public is already familiar. Now over the same piece of tinfoil he

whistled "Yankee Doodle," and reproduced the poetry and whistling together, yet each as distinct as though one person were whistling while another spoke. Then the same sheet he cackled and crowed and reproduced, as before, the three notes. Again and once or fourth time he went over the foil, this time calling in base tones and rolling "r's," "Hub-a-dub-dub," and to a rich, the fellow, the baker, the candlestick maker, all jumped out of a rotten potato; one, two, three, four, five, six, seven, eight, nine, ten." The phonograph quartette now repeated "Singer, on the hills," whistling, cackling, and called "Hub-a-dub-dub," all together, and with nearly as much distinctness as four different voices speaking at the same time could have done it. Then the whole was given backward—a frightful medley! Yet the whistling, though somewhat diminished, was distinct. Alternately and "Yankee Doodle" was whistled and given backward, and the effect was ludicrous.

Mr. Edison has not yet completed his experiments in the phonograph, for in the absence, during the afternoon, one of his assistants mildly called it a "mad dog" and turning the cylinder backward was answered in a shockingly profane manner.

This property of repeating sounds backward will doubtless be of great acoustic value in the future. "Once, when I had a little Indian, John Brown had a little Indian, John Brown had a little Indian boy." was sung so that in the words would be repeated, and in its reproduction the words would be heard in their proper order except backward, as the sound struck the drum and tore the tin foil. Immediately a screwdriver readjusted the machine and the "Wandering Refugee" was sung in a fine bass voice. Then, over this sheet, Mr. Edison sang it again, in a different tone, and the phonograph repeating both parts, imitated the company in a duet. "There," said Mr. Edison, "it is it's every one that can

SING A DUET ALONE."

Then upon a clear piece of tinfoil he sang and whistled, and another duet was given, though there was lack of harmony, for this reason, and it shows a most wonderful property in the instrument—As the operator sings the second tone he hears the first one, which he has by the force of vibration, and this runs through the same vibrating plate that he is receiving the new tone. The same plate is passing vibrations by repulsion upon the foil while it is transmitting, or speaking from the same foil the first record. In this instance, the whistling being so much sharper, prevented the use of the whistling hearing exactly the first air, and thus unison or harmony was not obtained.

Mr. Johnson laughed into the instrument so that the machine would laugh through the tinfoil, perpetuating it for several inches. Nevertheless it returned the laugh when reproduced Mr. Edison's coughing, blowing and sneezing. Mr. Charles Batchelor, the inventor's assistant, now entered, and Mr. Batchelor was engaged with a double mouthpiece, and placing their heads close together, Mr. Batchelor and Mr. Edison sang "John Brown's body lies a-mouldering in the grave," etc. No purer tones or clearer harmony would be asked in a concert room than that with which the phonograph reeled off the song. Regarding the mechanism, it were a musical treat to watch the machine at work. The writer bore away his piece of tinfoil as a trophy.

The little wonder-working instrument was re viewed in each different performance—was then made to speak in Greek, in French, in German, in "My get the best reading Latin," and in English, "and the poorest in English." Then he scratched on full after the explanation, which he called "scrutinizing the record." The voice in the reproduction was not so distinct, but each word could be understood. "I make it talk hoarse, that way," said he.

ITS CAPACITY.

"How far does a word extend on the foil?"

"Well, let me see. Phonographic words, that extends once around the cylinder, and there are 600 utterances for that word."

Then Mr. Edison spoke through the funnel—about a foot in length; then off a foot from the funnel, or two feet from the instrument. The repetitions were clear. "With a pasteboard diaphragm," said he, "which is much more sensitive than iron, I can speak into it from a distance of six feet and can talk into it twelve feet. I think I shall use a paper diaphragm on the regular machine." Turning it slowly by hand he spoke into it again, and then worked it fast so that the sound became a whistle instead of articulate speech.

"We had two machines together here the other day," said he, "and connecting the diaphragms with a rubber tube, ground off from one machine, the sound was taken up and whistled through the tube and registered on the other. Then we reproduced the speech from the second machine, turning it slowly. When it was turned the cylinder slowly that tenor-three words were recorded in two revolutions. Then the same were recorded in less than half a revolution. That was at the rate of forty-five words a revolution; there are sixteen threads to an inch, and the cylinder is eight inches.

This calculation allowed for 2100 words upon one cylinder foil, that covering, or about three columns of the Transcript. "I can do that as it is now," said he, "and can have two hundred threads to an inch and double the length of the cylinder, twelve times as many words, or 25,200. That is equal to the matter of a fifty-cent novel."

THE PHONOGRAPH.

When Mr. Edison was showing some results of his invent'gations in Philadelphia, some one jocosely remarked, "Why don't you invent a machine to talk a hole through a board." He thought a moment and replied, "I guess I can." He ordered boxes and constructed a small phonometer, and when the company now turned to look at the card on shown was a vibratory plate with a hole through the centre. Into the centre of it with a needle point like causes of the plate moved the ratchet wheel, and the ratchet wheels attached upon the same shaft. Several of the visitors spoke against the plate, and sent the wheel whirling at a rapid rate. Nothing being nor say other force except the human voice would move it.

THE MOTOPHONE,

or sound engine, was a curious musical instrument. A harp had been set up with an almost square frame upon the end of a bench. To the centre of its STRING[illegible] board was attached a bar which brought its centre in contact with the centre of a small disk. Upon the end of about fifteen pounds upon the foot of a lever, which, when it struck a string of the harp, sent the disk whirling. The passed from a motor. A current of electricity was then sent through the wheel. Mr. Batchelor, being several miles through a telephone, and they were repeated by the harp—the musical tones only. At the same time Mr. Edison revolved the small wheel and gradually drew out the electricity-prepared paper. He explained that this machine was vibrated by the action of electricity increasing and decreasing the friction upon the strip of paper. When the paper was drawn out slowly the motor was set up a vibratory motion, and the sounds given out were low and deep. If drawn out, it slightly, the sounds were the same reflected in the semitones. A current being suddenly reduced the friction, and the bar sprang back, vibrating the sounding-board. The machine is capable of 30,000 vibrations a second. It should be remembered that the Edison telephone is merely the increasing and decreasing of the force of an electric current by sound vibrations. Why electricity diminished the friction, and why it increased it, no one knows, but the fact is that a piece of potassium, which acted on the paper, but he had tried 28,000 chemicals and chemical combinations, and none increased or took the "friction against the paper. Only salts were of use. It will work well, and the more alkaline the better it is. The same principle was shown in other electrical apparatus. The practical purposes, however,

THE HARMONIC TELEGRAPH.

"What is this, Mr. Edison?" said one of the party, pointing to a horseshoe magnet with a bent bar of iron four and a half feet long—with a tiny dress-pound weights on each end. "Only that, my dear harmonic anglus," said the inventor, well pleased with the question. "It is really a large tuning fork. I can utilize its vibrations by connecting it with a battery of four cells so as to make it pause a dozen bursts of water three stories high, in a sky-four hours. I mean to apply it some day to the pumping of water for gentlemen's country residences. It can do as a matter of three cents a day—the expenses of four batteries." He set the bar into vibratory motion, by connecting the current. It was then an electro-magnetic instrument. A motion, and of about the force of one-horse power. The oscillations were about an eighth of an inch. The bar was not long-opened and closed the electric current in unison. The vibration, in this case as visible as the eye could oscillations, were at the rate of thirty-five a second. Mr. Edison declared he could make it run by sewing machine in the ordinary possible manner, for there was nothing to get out of order, the longest opening and closing its own circuit. But he said he would be obliged to have two [illegible]-bars—one, if necessary, a "dummy"—being an equal power, so as to preserve the [illegible] vibrations, for if reached to one end than to the other, the result would be the destruction of vibrations, in proportion to the unevenness of the powers, just as the tuning fork the vibration is destroyed if the ends of the fork are not evenly weighted. For the pumping machine the two pumps might sometimes be said to be tuned. Mr. Edison said that theoretically he got nine-tenths of the power of the machinery with this machine. All other machines, he said, lost two-thirds of the power of the battery, theoretically speaking.

Mr. Edison now turned to the visitors with a practical application of one of his inventions, the electric pen. This is a pen which, even if quite rapidly moved over the paper, cuts a line by means of a needle moved rapidly up and down in the pen case by an electric motor. From this almost impression are taken by the common printing process. The saver's telegraph and a picture traced from an illustrated weekly, all done by the electric pen or stylus, were handed each one of the party.

THE HUGHES TELEPHONE

was next exhibited and explained with the utmost frankness. It is entirely different in principle from the Bell telephone. Such inventors worked at the same time on different principles, and produced the same practical results almost simultaneously. Bell's telephone employs either a permanent magnet or an electro magnet, and the vibrations of sound are transmitted by means of a disturbance of the magnetic field, as in the magneto fork. Edison's method depends on variations in resistance or diminish—the resistance of passing galvanic electricity. The latter is by means of placing a disk of pressed carbon, about the size of a small quarter, between two platinum disks, healed a tympanum or vibrating plate, and the pressure of the loose at the voice compressing the carbon disk regulates the current of electricity passing through it, and the sensitiveness of a disk at the other end, vibrates another tympanum, reproducing the sound. Mr. Edison's telephone was spoken through the mouthpiece attached to the battery of four cells. According to the laws of the sciences, it is conceded that the Hughes would reproduce a sound giving it at times more force than the Bell telephone. Mr. Edison used other apparatus utilizing the sensitiveness of carbon to heat and pressure. Attaching a telephone to a galvanometer he pressed the tympanum with his finger, and the needle moved, the pressure increasing the resistance and diminishing the current. The weight of the plate on the carbon disk, to produce. Mr. Edison started experiments in this direction in 1875. In his first telephones he used rubber, but the heat of the hand, so sensitive was the carbon, made it necessary to substitute iron, and then to discard a handle altogether. Brass was found to be more sensitive than iron; then iron plate to be used in the place of the soft instead of brass. The thermopile, the next instrument for measuring heat, said Mr. Edison, is as sensitive as the sensitive as this carbon. With it and

THE BEAT OF A MAN

of the first magnitude he can almost open and close a galvanometer circuit. When he leaves the room the needle moves. He can detect the heat of a person after he talked to Mr. Batchelor through the. The latter called out, "What are you doing there? Where do you get that music?" "Here's it got any music," said Edison. But a clear musical tone was heard about once in every five seconds by Mr. Batchelor. Investigation showed that the contraction of the molecules in cooling produced what had probably never before been heard—molecular musical tones, then caused molecular music.

The carbon is obtained by burning benzine and rigolene. Benzine is, lampblack is not black at all. Many more things were shown and explained, which, though they did not weary the writer, might weary the reader.

THE TELETHERMOPHONE.

to do for the eye what the telephone does for the ear, and upon which the introduction to the astonishing waves of sound for waves of heat, was explained. With three-the receivers and communicators must be different—conversation has been carried on a mile. The sound is shot out of a bore formed like a bullet from a rifle barrel, and must be aimed correctly to produce an effect. Mr. Edison pointed to a tree an eighth of a mile distant, and said he had heard the clamour of a row under it from his laboratory window.

After a pleasant visit to the Edison family, the company took its departure, joining in a regular "Tiger" for the "Wizard of Menlo Park." As many friends as room, if possible, the mind that wears its head concealed his Exposition manner, and the "Tiger" was given with a will.

Thanks are due to Mr. William McMahon, the manager of the Edison Phonograph Exhibition Company, for the courtesy and instruction of this entr'acte-to-be-considered visit to Menlo Park.

Boston Journal.
WITH SUPPLEMENT.
SATURDAY MORNING, MAY 29, 1878.

EDISON AND HIS INVENTIONS.

MORE ABOUT THE "WIZARD" AND HIS LABORATORY.

One full article describing the Menlo Journal of Thomas A. Edison at Menlo Park would be a volume of itself. Edison at Menlo Park would be a volume of itself. Nearly to a description of the principles of the phonograph, the telephone, the microphone, with the latter there are also experiments, revealing to be presented. In regard to it it is now made there are 16 threads or gratings of the cloth, and as each thread is 100 wires, or filaments, that, through, or, rather, over 1,600 wires, or filaments, help to speak the voice. The whole cloth is about two inches square, and the telephone is complete. The receiver is also improved, and it is now so arranged that in an extended distance the words would not be unintelligible, the message, and coupled, therefore, but one-tenth of a millionth. The strange result of the experiment is that the articulation is clearer at a distance than when the receiver is held close to the mouth. Words which may be recorded upon a cylinder phonograph before upon the metal disk, reproduce, as a matter of fact, by drawing the cylinder-record lever before the cylinder eight inches instead of a record of eight words would be spoken. The two pictures above, as reproduced on the photograph, are modified representations of two of Edison's latest inventions of the cylinder. One record is made into a tin very fine sheets and the reading is done by a phonograph exactly like that with the metal is but a fraction of a millimeter thick, so that any have been spoken, and the production of a whistling sound. The machine, however, is a source of a similar connection between the mouthpiece of the speaking instrument and that of a receiving one will make a record that can be similarly spoken. Edison has also invented a new form of the original Morse alphabet for the use of telegraphers, requiring, however, only a rapidity when used by skilled hands. This is what Mr. Edison himself says: "I would like to talk to each other." One of the greatest difficulties Edison finds in connection with the phonograph is that of getting the cylinder exactly and the letters in which the sound is recorded are distinctly shaped to the ear. The cylinder per makes a record, and if the slightest variation occurs, and the phonograph is at all at work receiving, the produced will cause a record that would sound like a confused mixture of sound of thing. The latest information, and that personally given, is all derived from Edison himself.

WHAT IS DONE NOW WITH THE PHONOGRAPH.

If only half that has been told were true the phonograph would be a great curiosity, but as it is at present can be demonstrated with exactness not enough that the inventor should be a 'valuable article' for entertainments. Though the idea of a megaph company has been in existence but a few months, it has already had a large number of applications for the use of the instrument which to exhibit it. In many places in America, in Canada, in Australia, and in other parts of the world exhibitions are already at work, reaping a percentage of their profits to the company, and in a few months the number will be greatly increased. This is the only way to utilize the invention for the present, save to the company, but the return is a profitableness. Edison has also received from the Emperor of Germany addressed here a facsimile, the message addressed at Hartlebottom itself since Mr. Wilhelm Siemaltin service of the whole nation, and the correspondence per day. The phonograph has been to unite a good deal of the time of Mr. Edison's performances to the representation of current playing.

THE MICROPHONE.

After having shown what could have proved to him a thousand times of experiments upon the phonograph, and answered a thousand questions, Mr. Edison next proceeded to show the microphone, which were invented him several times in various forms. Mr. Edison took his visitors into the room where the telephone apparatus was. As described, this instrument is a sounding board, over which are stretched wires representing the notes of a piano. Underneath the wires are magnets. To the sounding board is a speaking tube, through which any one may talk a sounding wheel. The connection with the wheel and the apparatus is maintained by a platinum point dipping into a cup of mercury. The wheel is revolving, the mercury flowing this point in the cup, and the current is broken. Now, when the instrument is in use, and the key projecting from the sounding board, a sawyer strikes at other, the vibrations are carried to the wires, and the magnets are sent such that the motion is somewhat approximating under the bar causes the sounding board to vibrate, whose force should be so adequate to the current, at which time the sender alternatively and broken alternately by vibrations in the telephone. The vibrations in the sounding board correspond, and are exactly like those of the speaker's voice, and the receiving ear or ear of the attached wire. Mr. Edison was seen with what we may call the sympathy of those who have not seen it, and the instrument is connected to the outside wire. The experiment discerning that was a pleasing one, Mr. Edison's voice was heard in the room through the telephone, and the instrument under inspection reproducing the words with much distinctness. Mr. Edison then explained to his visitors that Mr. Edison made no invention capable of expectations in the progress of developing the idea which is to be a telephone, and that the instrument is the invention of no person that wants to use, or to use his own words, "not worth five cents, except as a toy or a thing."

THE LOUD-SPEAKING TELEPHONE.

Another invention being of Edison established to his genius of great benefit of practical value, but to be a loud speaker, sensitiveness, and modified from an ordinary telephone. Mr. Edison has made a number of these of Edison's devising to the public, asserting that "no one is either deaf or being deafed, the receiver of the loud-speaking telephone is something of a disposition to hear." He seems disposed to be taking as they are considered, and the receiver is not to be used in connection with these principles that he intended as a speaking one, but that it is not to be used in connection with the phonograph. "I would rather be rolled," he said, "than to be deafened." There are probably few persons who have seen the record of the phonograph, or a series of disks, following the experiments given below the fact, for the sake of convenience, whether he desired to have words with half a millionth. One of these words which may be recorded upon a cylinder dressed of the cylinder during the experiment

catching the sound, conveying it through the air-chambers and increasing it at every stage until it reaches the ear. Edison's description of it was, "it makes one's ear feel as big as a house." The speaking apparatus consists of a long tube reaching into an air-chamber, and through the ce" "rth of this tube is run a spiral wire. At the end of the tube is placed a large" "l-shaped fennel. The action of the spiral wire is to give to the sound, as emitted from the mouth, a revolving motion, similar to that given to a ball shot from a grooved rifle. By this means, and also passing through the air-chamber, he is enabled to throw the sound to an almost incredible distance. Two men, each with one of these machines, have talked with each other two miles apart, and a person talking in the trumpet in an ordinary tone of voice can be distinctly understood at the distance of a mile. Mr. Edison repeated several instances of the performance of this machine, which I will not have space to narrate. There is one thing that can be relied upon, however; this is not to be the last of the many wonders that spring into reality through the skillful ingenuity of the wonderful Edison. The man seems to have no end of ideas, and when he once gets the idea it is sure to be carried out.

There is a lively interest shown by the New York public at present, as to the probabilities of a war between England and Russia, and I must confess that a large majority show a strong feeling of friendship toward Russia, and many expressions of satisfaction are heard upon every hand that she has succeeded in maintaining her position in the diplomatic negotiations which have been carried on during the past six weeks. Russia has taken pains to have it distinctly understood that in case of war the first blow will be struck at England's commerce, and her transactions in this vicinity show that it is no idle threat. During the last week Russian agents have completed negotiations for the new Pacific Mail steamer, "State of California," the "Columbus" of Clyde's line to Havana, and the celebrated schooner-yacht "[illegible]." The "California," was launched at Philadelphia May 16th, and was originally intended to be placed on the Pacific Mail line, running from San Francisco. She was built expressly for speed—the builders guaranteeing six-teen knots an hour—for the purpose of beating the "State of Oregon," of the opposition line. She is now being plowed for guns, and will make a dangerous cruiser for British shipping interests. The "Columbus" is one of the fastest steamships that runs from this port. The Russian agents paid $110,000 for her. She is to be brought to this city and work commenced immediately. Of the short and tragic career of the "Mohawk" there is more to say. She was built about three years ago by the late Commodore William T. Garner, of the New York yacht club, and cost, complete, $175,000. This yacht is 144 feet long and carries the enormous spread of 22,000 square feet of canvas. In 1870, while at her anchorage opposite Staten Island, through the negligence of the sailing-master, who allowed her sails to be hoisted while at anchor and the centerboard up, she was struck by a squall and careened suddenly over. From the fact that the lead ballast was not properly secured, it was impossible to right her and she went to the bottom, drowning Commodore Garner, his wife, Frost Thorn and Miss Hunter, who were in the cabin. The yacht was afterward raised, but has never since been used. Notwithstanding this accident, she is considered a remarkably seaworthy boat, and will go into the dry-dock immediately and be cleaned and painted. An auxiliary screw will be put in her and then sealed for sea. The price paid was only $25,000. The yacht is capable of carrying two heavy guns, as she is very solid, and it is not very probable that any English war-vessel could overtake her either in fair weather or foul.

It is evidently the intention of James Gordon Bennett to return to this country before long, for the true story of his duel with Fred. Mc" who publicly cowhided him, has lately been made public by one of the seconds of the affair. It seems that at the first fire both Bennett and Bennett's pistol only escaped; then Bennett's second then demanded a return fire, which was accorded by Mc" and his second. Bennett then fired into the air, and the principals shook hands and left the grounds in different directions. Fred May proceeded to Washington and James Gordon Bennett to Europe, and so ended the duel. There comes a whisper from over the Atlantic that his sister, Jennette, who has been doing the honors of his establishment in Paris, is engaged to be married to an Irish peer [illegible] complications. The year is quiet on Broadway, and Commodore Bennett is a bachelor, but it is to be presumed that there will not be wanting in this case those mutual concessions so necessary for the happiness of the married state.

An Hour With the Phonograph.

Last Friday afternoon we spent a very pleasant hour in Horticultural Hall, Boston, listening to the wonderful speaking phonograph, recently invented by Mr. Edison. It is indeed a wonder, and rivals the telephone in its claims to be the most wonderful invention of the past few years. It is marvelous that a thing with nothing not much larger than an apple-corer can repeat what is said to it with such distinctness, simply by the turning of a crank. There is a cylinder to which the crank is attached, also a mouthpiece which can be raised or detached from this cylinder. This mouthpiece contains a piece of ferrotype plate, about 1½ inches in diameter, and is dampened and clamped between two rings. There are pieces of india-rubber pressed in between these two rings so that the ferrotype cannot sound its fundamental notes, but will only respond to what are called forced vibrations. Upon the under surface of this piece there is a little steel point which is attached to the plate by means of a rubber ring intervening between the plate and the steel point. When the lips are placed at the opening in the mouth-piece, the vibrations of sound produced in speaking will be communicated on the plate, thus causing the steel point to be depressed and raised, these motions succeeding each other with a rapidity depending upon the rate of vibrations in a given tone of the voice.

The cylinder is grooved with a spiral thread. The steel point impinges in the depression or grooves of the cylinder upon which a sheet of tinfoil has been attached. As the cylinder is turned, the point traces the spiral on the whole of the surface covered with the foil. You talk against the plate, and by simply reversing the motion of the crank it will repeat what was said.

The experiments were intensely interesting. The operator repeated the familiar poem,

> "Mary had a little lamb,
> Its fleece was white as snow,"

and immediately as he reversed the crank, it was repeated through a tarnished tunnel, obeying all the inflections of his voice. A correct player performed several tunes, placing his cornet over the mouth-piece, and they were all repeated with wonderful accuracy. Some one sang in the mouth-piece and the singing was reproduced. Imitations of crowing, barking, cat calls, whistling and singing, were also repeated, affording much mirth. The possibilities of the invention seem almost infinite, and songs once sung into its mouth-piece, addresses or readings by distinguished persons, messages from loved friends, may be repeated at will years after they have been uttered, as the tin foil containing the impressions can be kept, numbered and reproduced whenever wanted.

—A suffering father wants Edison to invent some kind of a phone or graf that would be acted on by the cry of an infant in the night, so it would instantly grow the cradle and rock like the tender billows on the ocean's breast.

March 24, 1878

"THE TELEPHONE."

He is a Great Man Now.

Mr. Edison, as a yo" " telegraph operator at Memphis, " known for the quaint drawings with which, in odd leisure moments, he illustrated the Southern Press reports. One habit was to convert the tails of his g's and y's into faces, with the most ludicrous expression imaginable.— Another habit was to draw a railroad curve around a ball, with a train of cars at full speed; on the first car was a T, on the second Y, and so on until Tyler, the signature of the report, was spelled out, and the last car, " " " perceptible round the curve, " " on, or think. This continued for some time, until a Memphis editor published a paragraph praising in highest terms the talents of the sketches, but objecting to them on the ground that the printers took up too much time admiring and [illegible] in trying to find correspondence with to-morrow's news. This was the last of the "illustrated press reports," as Edison was called.

Mr. Edison says that, in fact, out two of his most skilful assistants, at work testing his plans in regard to an apparatus for the deaf. The assistants let him forward on the subject of such an apparatus, assuring him that the second ear to be used, [illegible] moans. He feels sure that he can produce a practical [illegible] affirmative.

GLOUCESTER EVENING TELEGRAPH

TUESDAY, MAY 28, 1878

THE "MODERN MIRACLE".

Arrival of One of Edison's Talking Machines in This City—Description of the Instrument—How it Works—Some of its Utterances, etc., etc.

The phonograph has come. The most bizarre, the most startling, the most perfect. The creation was born, reared up in a day and manifested its unlimited faculties. It does not claim to be dead to all thought of visitors and is apparently perfectly [illegible] ate "for" [illegible] to approval and favor. Insofar, but there is no [illegible] to the fact that it is the most remarkable, curious, At times now Watson's public will soon be accorded the privilege of wondering with open-mouthed amazement.

THE INSTRUMENT,

or instruments—for there are three of them—are in the possession of Mr. George H. Bliss, General Manager of the Western Electric Manufacturing Company, a friend of Edison, the inventor. Was, as previously stated in, The JOURNAL,

has now awarded the privileges of exhibiting the modern miracle in Illinois. They arrived yesterday afternoon, and established themselves in the Methodist Church Block, from which it was deemed probable that they would be unable to effect an escape. They are the very first of their genus that have ever been brought to the part of the country, and, of course, their keeper is especially careful of the "critters."

This morning, when the cover was carefully removed from the box, the reporter drew near and eagerly looked in, but immediately started back, expecting the thing to jump.

"Don't be afraid," said Mr. Bliss; "it won't bite."

Whereupon Mr. Chase, a friend of Mr. Bliss, and the reporter were sufficiently reassured to allow Mr. Bliss to remove the machine from its lair, and place it on the table for the inspection of it, combined with its several motives, as it was observed to be entirely harmless, served to show that it consisted of

AN IRON CYLINDER,

about five inches in diameter and six in length, into which was cast an ordinary record, such as is used in the phonograph. This cylinder was sprung on an axis, projecting at each end about the length of the cylinder, and also elevated by a screw thread corresponding to that on the cylinder. Over the cylinder, and so arranged that a small rod, by the pressure of the cylinder could be revolved, so as to rub rod-fashion on the axis-supports. The mouth-piece is a small round piece of thin tin, having a concave surface on which to catch the sound, supported by a metallic arm, and fixed to the frame-work in close proximity to the cylinder. Fixed to the under side of this mouth-piece, by means of cement, is a minute

EIGHTY-SEVEN NEEDLE

which, when the cylinder is made to revolve under, would impinge into the cover thereof thereon. This was the simple contrivance. Now, in order to

MAKE IT SPEAK,

all that was necessary was to wind the cylinder with a key-crank on the left, to-screw on the ends of the cylinder, and to set the machine in motion, so that the cylinder is revolved to one end of the frame, and the mouth-piece is brought close to the cylinder, the latter being very nicely adjusted against the needle. The machine being in motion into the mouth-piece, the cylinder is slowly revolved; the plate in which the needle is attached vibrates in correspond with the valleys and the hills of the record, and, in turn, nothing such indentations into the cover of the screw, so that it is clear out over the room though very small. The speaking having been concluded, the mouth-piece is swung back, and the cylinder is screwed back to where it was. A large tin funnel is then attached to the mouth-piece, which is swung back to the cylinder. This funnel is designed to gather and send out the sounds as they issue from the instrument; the crank is turned, the needle moves over its former course, the little needle strikes into the indentations, and, rather than vibrating the tin plate of the mouth-piece previously as it was originally found voice. And—to our behalf, the machine spoke! That is all there is to it. It was not a little startling, but a distinct and recognizable friend's eccentricity of speech. The machine sometimes receives a tone or hybrid voice sometimes readily than a bass. Last evening the machine was interviewed numerously, was put into requisition to the gratification of the First Methodist Church.

"Wonderful invention, indeed!" remarked Mr. Bliss, "and I can vouch for the authenticity of that sentiment.

"Several persons who witnessed the exhibition last somebody had imagined as Mr. Bliss' particular exclamation. Others were astounded while getting out the machinery, in such a manner as would not have surprised any one familiar with the machine.

It seemed with the real spirit and tongue such expressions as "Let me alone," "I'll go you my mother knew me by," and numberless other Americanisms, and as to whether the small company had been provoked by him, being had provoked by him, being had provoked by him, emphatically

Ludwigshafener Anzeiger.

Dienstag, den 7. Mai 1878.

Das Bürgermeisteramt. Sg. Kutterer.

Ludwigshafen, 7. Mai. Wir hatten Gelegenheit, den Vortrag des Herrn Sprachlehrers **Sprenger** über Telephon und Phonographh gestern Abend beizuwohnen, und gehen daher ein kurzes Referat über denselben hier wieder. Nachdem der Vortragende die Erfindung des Telephon, wie den Erfinder Bell und die Einführung des Letzteren geschildert, und wie dieser einfache Apparat anfänglich Aufsehen erregte, ging er über auf den Phonographh oder den Sprechwiedersprecher, und gleichte seinen Vortrag in der Biographie des Erfinders zusammen, George H. Edison. Nachdem Redner die verschiedenen Stadien in den Versuchen Edison's charakterisirt, sowohl als späterer Rekorder, Telegraphist, wie privatim, und wie eine wahre Manie in Fleiß und Thätigkeit und eine Erfindungsgabe in ihm zu Tage getreten sei, so daß er nach einander den Automatischen Telegraphen, Quadruplex und Sextuplex T., den Carbon-Telephon, die elektrische Feder, den Mikrophon (Lautsprecher), den Electric-Motographen erfand und auf diese Erfindungen Patente erhielt, ging Redner auf die Beschreibung des Phonographen über, welche und welches zu weit führen würde, hier weiter zu gehen. Genügen wollen wir nur noch, daß selbiger in der Academie der science in Paris, wie in Newyork, als ein Wunder und epochemachendes Werk in unserm achtundzwanzigsten Jahrhundert betrachtet wird und es auch stellt sich die Verwirklichung denselben, ib. — Dem Herrn Sprenger aber legen wir unsern bezüglich Dank für seinen interessanten Vortrag und hätten wir gewünscht, daß er sich eingehender über die einzelnen Manipulationen bei der Vervollständigung der Stimmenmiedergabe auszusprechen hätte, mangelt Augenscheinlichkeit wohl in dem Mangel an praktischen Beispielen seinem Grund haben dürfte.

Mannheim, 6. Mai. Das großherzogliche Regierungsamt erläßt folgender gelegentlich Bekanntmachung, den Verkauf von Blumen, Bouquets u. dgl. durch Kinder an öffentlichen Orten betreffend: Da in hiesiger Stadt unserer bisher immer mehr die Unsitte überhand nimmt, daß schul-

Note Field and Shakespeare.

London, May 22.—A performance was given in aid of the Shakespeare Memorial Theater, Stratford-on-Avon, which has been established at Stratford-on-Avon, at the Opera Comique, this afternoon. The performance was arranged by Mrs. Kate Field, and included the following features: Selections from "Hamlet" and Julius "As You Like It," "Romeo and Juliet," "Much Ado About Nothing," which concluded with Miss Field on the stage, in which she recited "Much Ado About Nothing," which concluded with "Much Ado About Nothing," which concluded with "Much Ado About Nothing," which concluded with

The Philadelphia Times

PHILADELPHIA, MAY 27, 1878.

The Daily Circulation of THE TIMES exceeds that of ALL the other Philadelphia Morning Papers COMBINED, except one.

A Great Journalistic Combat.

From the Baltimore Gazette.

One of the most sanguinary struggles that ever occurred in the history of the press the invasion by the British troops, in 1814, took place in the picture gallery of the House on Friday last, Mr. Uriah Hyde Thompson, of the Philadelphia Times, and Mr. Gilbert Hart, of the Philadelphia Record, met on the floor, provided with swords, and selected him if he had written a certain article which had appeared in the paper which he represented. Instead of the paper being represented by the editorial or managing editor, Gilbert Hart, whose courage was admitted in the office of the Baltimore Gazette, acknowledged himself to be the writer. Without saying a word Mr. Painter struck him in the face with the back of his hand, knocking out thirteen teeth and cutting his mouth terribly. Mr. Hart then closed with Mr. Painter with fierce fury, breaking his sword entirely off about at the handle region, and receiving a wound reported at 7 o'clock of the left shoulder. Mr. Painter, seeing that Mr. Hart was disposed promptly to let fast and broke Mr. Painter with the club, breaking his forearm in six pieces and rendering him helpless. Mr. Painter was carried off by the auxiliary reporter and assigned on the floor of the gallery with his body. Then he proceeded to the body of Mr. Hart, who was lying on the floor in a pool of blood, and, placing his knee on his throat, smashed his fingers, and was proceeding to administer on his other hand plaudits when Mr. Gilbert, of the Sun, which, shows for everybody, interfered, and declared that the fight was over, and that it was enough for the bloody work. After the struggle was over, it was found that the southern wall of the gallery was literally covered with blood, and the floor had suffered a distribution of intrenal fats and fibrous lectics.

EDISON'S LABORATORY.

To most people the birth of inventions and the steps of inventors have been shrouded in mystery and covered with the hazy glamor of the improbable; and it is with a certain sense of curiosity, not unmixed with awe, that one finds himself for the first time standing on the porch of the weather-stained wooden building at Menlo Park known as "Edison's Laboratory." The whir of wheels and the clank of machinery comes from the inside, while across the grassy field is seen a man slowly approaching who is pointed out as Mr. Edison. Our business once made known to the great inventor, we are treated with the utmost politeness and admitted to the world of wonders within.

The Phonograph is our first objective point. It is the one used by Mr. Edison himself when experimenting with a view to improvements; and as he is an untiring worker the instrument suffers disarrangement and readjustment many times during the twenty-four hours. As we approached, a master hand put it in order. A brass cylinder is grooved with a spiral, and moves along, as well as around its axis, in such a manner that a stationary needle-point follows the depressions accurately from end to end. The needle-point is fixed to a disc of metal which is surrounded by a small wooden frame. The cylinder is now covered smoothly with a sheet of tin-foil and the Phonograph is ready to use. The attendant favors us with a solo, then lifts the needle and places it in its original position. The tinfoil, now covered with marks of the needle, is said by the attendant to contain the necessary elements for the reproduction of the song without the aid of the human voice. In a moment the statement is proved, and as, with distinct tone and modulation, John Brown's soul goes marching along the cylinder we realize that this is an age of inventions and the Phonograph not the least of them. After experimenting with whistling, singing and talking, we are invited to try it. The poets are called upon to contribute, and soon

"It was many and many a year ago
In a kingdom by the sea,"

and "Hickory, dickory, dock, the mouse ran up the clock," resound shrilly through the laboratory. The machine, as the inventor expresses it, "is yet an infant," and its future career implies many things still unheard of. As the inanimate instrument articulates words with the distinctness of a human being, the observer is forcibly reminded of the medieval legend of Albertus Magnus and his "Brazen Head," which chattered so fast that Thomas Aquinas, his pupil, took up a hammer and broke it in pieces. Mr. Edison has fifteen or twenty skilled workmen busy all the time working at his plans and models. His own work is done in the night, the time, in his opinion, best fitted for head work. The appearance of the laboratory alone affords evidence of serious work. The tables are covered with musical instruments, batteries, coils, magnets, crucibles, retorts, and a thousand and one things that an experimenter delights in. The shelves are filled with numberless chemicals, and the apparatus, as well as the application of chemistry to aid electricity, tells the observer that Mr. Edison is an original investigator in that line. The things, however, that show the true character of the place are the undeveloped machines, the brass and iron representations of abandoned projects, the gigantic ideas partially materialized, and the many things in process of construction. They illustrate the enormous fertility, the unceasing toil, and the acute working of the brain that conceived them. They suggest the possibilities of vast future progress. They hint at powers of man as yet unthought of, and lie there, mute emblems of the force of a busy American mind, only wanting the lever of the ancient Greek to raise the world from its foundations.

NEW-BRUNSWICK:
TUESDAY, MAY 28, 1878.

SOUND AND ELECTRICITY.

MR. EDISON calls his Phonograph "an infant." Infants are not usually so wonderful in their simplicity or marvelous in their developments; and had Mr. EDISON lived in 1778 instead of 1878, his "infant" would doubtless have cost him his life at the faggot or the rack. It must be evident to every observing mind that we are but upon the threshhold of discoveries in the line of the Phonograph, the Telephone and Electricity. Kindred to those subjects, and forming a part of their philosophic developments, comes the Microphone, by which, according to Professor D. E. Hughes, before the Royal Society of London, sounds are so multiplied and intensified that the footsteps of a house-fly become distinctly audible; and the slightest sound may be intensified, and transmitted to almost any distance by the Telephone. What Faraday's "inductive" electrical current is to the "continuous" current of the galvanic battery, the Microphone is to the Telephone. In both of these cases electricity is the prime factor.

Equally as marvellous are the developments of electricity as applied to the generation of light for illumination. An "electric light," manufactured in Cleveland and constructed for lighting up a large factory in Philadelphia, was exhibited a few days ago before several eminent scientists. Of this "light" and the results of its exhibition, the *Herald* says:

It consists of a brush dynamo-electric machine of 10,000 candle power, arranged to give four separate currents, each running an electric lamp of 2,500 candle power. Two of the lamps were placed on the third and two on the fourth floor of the immense building, and when the engine was started up the machine started at the same time, and, without the slightest manual interference, the lamps flashed out their light in all its magnificence. The effect was most brilliant. The rooms were dazzled with a pure white light like the light of the sun, and it streamed out at all the windows, illuminating houses and streets for a long distance in every direction. The light was very uniform and steady, free from the flickering that used to be an accompaniment of electric light, and, considering the enormous illuminating power, the light was unexpectedly soft and endurable to the eyes. An opportunity was afforded to test the character and whiteness of the light. Books, maps, charts, signals, etc., of brilliant colors were hanging against the wall at one side of the room, and it was decided that the colors were rendered as nearly as by the full light of the sun. Politicians were present to let the amount that the light furnished by the apparatus would cost, if used by the narrow company as it was used last evening, and it was ascertained that the total cost of the whole light from the four lamps, including the items of consumption of carbon in the lamps, interest on the investment, and wear and tear, would not exceed 30 cents per hour. The light produced was photometrically equal to 200 gas burners, burning five feet of gas per hour each. This amount of gas would cost $1 per hour.

From experiments made, and operative results actually gained, in Germany, Prussia, France, England and this country, electricity, as an illuminating agent, is destined, at no distant day, completely to supersede coal gas both in brilliancy and cost. Indeed, experiments already made demonstrate the fact that electricity, as an illuminator, can be introduced into dwellings and factories at a trifling expense, and save to the consumers more than one-half the present cost of gas.

THE PHONOGRAPH, ETC.

MR. EDISON AT HOME AT MENLO PARK

Description of a Visit.

A CURIOSITY SHOP OF WONDERS.

A 6 o'clock on Tuesday evening a merry party of representatives of the press, under the guardianship of Mr. William Mathews, the courteous manager of the Phonograph Bureau in Boston, together with Mr. Frank L. Stanley, took the train at the old Colony depot for Fall River. The press representation was as follows: Mr. Barnes of the *Advertiser*, Mr. Hallett of the *Globe*, Mr. Baron of the *Herald*, Mr. Webber of the *Journal*, Mr. Barnes of the *Transcript*, Mr. McNally of the Sunday Times, and a representative of the *Traveller*. The trip as far as Fall River was the same as it would be on any other occasion when a crowd of reporters get together; that is, full of wit and good humor.

At Fall River all got outside long at the wharf after the arrival of the train. Upon arriving in New York, the Boston party was met by Mr. J. H. Johnson, the general manager of the Phonograph Company, who accompanied them to Menlo Park. He was in furious requisition in the party, and quotes was piled upon quotes, while the air was filled with the best of anecdotes, and crowned with the fullest satisfaction. Inasmuch as much matter of news was gleaned which cannot fail to interest and instruct, the larger part of it will be given.

THE PHONOGRAPH COMPANY

has a capital of $300,000, and is made up of the following gentlemen: Mr. Gardner G. Hubbard and Mr. G. L. Bradford, of Cambridge, Mass., Mr. Charles A. Chevrier and Mr. Gilberte L. Roscoett of New York, Mr. N. H. Butler of Washington, D. C., Mr. Johnson and Mr. Edison. The company after organization paid Mr. Edison a royalty of $12,000 as a premium of said, and agreed to pay him 20 per cent. of the gross receipts from all sources. Almost all the territory in this country has been distributed out to agents, and in Europe with perfect South America and Canada. The control right for Great Britain was sold as a royalty basis to the Bonanza Company of London. The royalty on the Bonanza is probably to be considerably by Mr. Johnson and Mr. Bonnevill, a brother of Mr. Hubbard, and Mr. Edison, the latter of Mr. Hubbard's. Roosevelt, of the company. Mr. Edison has determined to sell no more machines, but to dispose of them on the royalty basis. Mr. Johnson explained the difference between the

KISSOG AND BELL TELEPHONE,

and it is very marked and important. When Mr. Bell came before the public with his invention, Mr. Edison was still experimenting with his. While Mr. Bell makes very impressive use of the magnet, Mr. Edison does not. Mr. Bell's method of using barrelled the induction. The telephone, like a microphone, has a receiving to supersede as a toy, and the Bell in this case was a natural instrument, invented in 1857 by Reis, a prominent scientist in Germany. Reis exhibited a diaphragm of his instrument. Mr. Gray, the late President of the Western Union Telegraph Company, presented Mr. Edison with a memorandum of the work. In Europe Mr. Edison went to Germany, Bell to England, and Reis to France. Everything, until he has completed the telephone. A receiver resembles of the Edison telephone is used not to give, but one thing must be said, and it is that in his work is required a very wonderful property of action, which Reis did not possess. Mr. Edison has a high ideal of perfection. He found that Reis's instrument was called backwards. So in the machine which he has invented. A membrane is placed between two magnets, and when the sound waves strike upon the membrane they vibrate, and against the upper face of the membrane. There is battery and the current is increased. Then the battery and the current is decreased. Then the battery and the current is increased. Then a battery and according to the number of times per second the battery is increased and decreased. Edison has brought the telephone to a whisper with his telephone from Philadelphia to New York, and Mr. Johnson has had his residence at Ft. Hamilton connected with the office. Also the principal points of the conversation with Mr. Johnson between Jersey City and

MENLO PARK.

This is a lovely, 25 miles from New York, and when the party arrived at eight from the train for that see no more than the depot. Mr. Edison was there to meet the party arrived, and they proceeded at once to the laboratory of Mr. Edison, and inasmuch as he was not in the best of health, and had been confined to the house for several days with his phonograph, Mr. Johnson went to summon him while the visitors took a look around the place.

The laboratory is a long, white, two-story building, situated on a hill, and given the appearance of being a country shop better. In the rear of the laboratory stands a very old apple tree around whose trunk Mr. Edison has erected a platform, and on it has placed machinery from the laboratory. In the front of the laboratory is a piazza on which was placed a number of chairs, and in which, whose star some East River bridge. It is surrounded with the bathroom and cellars, could be distinctly seen. Across the railroad run like a swarthy giant on the night before. Mr. Johnson's method of work, suggested the best idea that was conceived by Mr. Edison.

Of course there was a great deal to see and learn that the visit was to reflect a queer sort of a fellow, genius though he is, and the party was not disappointed as a whole in meeting. This time he was an unshaven and uncouthly gentleman, who strutted around the laboratory in a pair of pants, with the weakest suspenders the party has seen with the weakest suspenders the party has seen with the weakest suspenders the party has seen

would be his best and surest conductor of electricity, and the next evening he made the lesion from the paper. "Sweet be thy repose" was sung through the microphone with considerable beauty and power, and as other interesting and instructive inventions were made, but there is not room for their description.

IN CONCLUSION.

It was late in the afternoon that the party visited Edison's house, and could be found in as all that was accomplished.

It is situated a few rods from the laboratory and is a large, old-fashioned, gable-roofed structure. It is surrounded by a large yard, which is tastefully laid out with pathways, grass and trees and many artificial curiosities. "Edison's Folly" have made.

The house is not at present occupied as exclusively the dwelling of himself, as one would know, the owner does not put his eyes on both, that they were scarcely ever closed. There is a large family of wife, children, servants, and relatives. A full-blooded Newfoundland puppy and specimen. She is a blonde, and possesses a pair of blue eyes, full of expression and power.

Mrs. Edison, a boy and a girl, runs the house, and their presence, with the noise of children at play, would offer his father, a boy of seven years of age, and Alice by five years of age. They were both presented to the party, and the little girl shook hands with them all.

At three o'clock the party took the train for Jersey City, and at six o'clock last evening were on the Pennsylvania Railroad coming home. Upon the train, a cool and profitable evening was spent in discussing the manners of the visit. It was unanimously the opinion that a more committee, consisting of Mr. Edison, Mr. Vanderwort and his representative of the Daily Graphic, could not have been selected for the purpose, or less likely to make mistakes and to express the hope that he would visit Boston.

THE DAILY GRAPHIC

FRIDAY, MAY 31, 1878.

SCENES AMONG THE NUNS.

The convent was very cold yesterday afternoon when the "Graphic" of the Convent of Mount St. Vincent, on the Hudson, surrounded by people and crowds, to write "eye-witness" of the latest wonder of science, the telephone of Professor A. Edison Hughes. The "Graphic," the church, spiritual, dwelling as many as fourteen and a quarter world, the exhibitor, shrewd, learned, practical, audacious, cutting truthful and not pretending to know or care anything about any world but this. Among the guests were Mr. Edison, Mr. Vanderwort, one of the inventor, F. G. Gilmore, of the "Graphic," Chas. Barnes, Dr. Richardson, of the Associated Press, Mr. Hughes, Professor Hughes, of the Associated Press, and several other well-known journalists. Mr. Edison was very warmly greeted by the Mother Superior, and seemed to feel quite at home. He was much interested in everything in the audience, except himself, and was constantly asking questions of the Sisters that embrace their manifold duties. He was particularly interested in the observatory, Edison's telephones and electric gong, and the kitchen, and the dining-room of the audience.

Having reached at the top, house about the new English invention for the transmission of sound, the party were shown into the large room, the walls of which were covered with pictures of the Mother Superior, the Sisters, and the pupils. Upon the walls were hung the telephones, and the electric gong, and the kitchen, and the dining-room of the audience.

Professor Hughes, the inventor of the type printing apparatus which goes by his name, has added another to the multiplying marvels of contemporary science. To the telephone and the phonograph, he has added the microphone. In some respect it approximates the Tyndallean sound that "carries" to the ear, and causes to sound in the same way that selenium is sensitive to light. That is to say, if we place three bodies in the circuit of a small battery and subject them to sound vibrations of other words, talk at them—the electric current is modified, producing through it will be so continuously modified as the voice that the object may be used instead of a telephone for sending a message.

In the last number of *Nature*, from which the above paragraph is extracted, Professor Hughes's little instrument is described at some length, in connection with experiments given by him before the Royal Society. He used a battery of three simple Bunsen's cells, and a telephone as a phenomenon of the present character. At first he used a stretched wire, but, thought that the vibrations talked at, no effect was marked until a breaking strain was applied; at the moment of breaking a sound was heard. Next the broken ends were pressed together. But in Professor Hughes's own words:

It was soon found that it was not at all necessary to join two wires endways together to reproduce sounds. Two pieces of wire placed vertically one on the other would do as well when their surfaces were in contact, and no matter how considerable a resistance to the current existed at the point where the contact was made, whether one or more portions of the electrical conductor were in the form of loose powder, or of a contact, by a slight pressure between them, sound could be heard. Wire terminals in two communicating circuits, one of platinum and the other of silver by a slight pressure, were exceedingly feeble, and by laying a similar pair between them, sound could be heard. Even when the platinum terminals were left lying on the table by their own weight, that a square coal—flannel on, using two of the latter, and by placing a sound plate on the vibrations were almost produced, the effect increased with the weight. Even when the surface of the wires was wanting, as in the following experiments the Geiger because more and more sensitive, such as water powder—a platinum, and nothing to be detected. Several other metallic powder, such as water powder—a platinum, and nothing to be detected. Several other metallic powders also metallic filings, placed at the points of contact, greatly added to the power of the instrument.

The Professor found that the material with the materials used. "All metals, however," says Professor Hughes, "could be made to possess this property, provided the division of the metal was sufficiently great, and that the material used does not oxidize by contact with the air during the experiments. Thus platinum and mercury are very sensitive and answering in their results, while lead soon becomes of such high resistance as to render communication upon the surface as to be unsatisfactory. A mass of height round about is peculiarly sensitive to sound, while clean, but as the skin soon becomes coated with oxide the sensitiveness ceases. Carbon, made from its surface being entirely free from contraction, is excellent, but the best results I have been able to obtain at present have been from mercury in a finely divided state. I took a comparatively porous conducting body, such as fine willow charcoal used by artists for sketching, heating it gradually on a white heat and then dipping it into mercury while it is incandescent. The mercury in the pores, caused by the sudden cooling, becomes fixed with innumerable minute globules of mercury, thus, as it were, isolating the mercury in a fine state of division. Some of the charcoal carbon treated in a similar manner with and without platinum deposited upon it, and the chloride of platinum, I have also found similar effects from the willow charcoal, heated in an atmosphere of hydrogen, to a white heat and containing a few particles of silver or silver easily reproduced metal. Under certain conditions, the willow carbon will be found to be metallized, having the metal distributed throughout its pores in a fine state of division. Iron also seems to enter the pores if heated to a white heat without being exposed to air, combined with the carbon, as in graphite, and, indeed, some of the best results have been obtained from what I call physical conducting pow ts a fine state of division."

MARVELS OF SCIENCE.

THE MICROPHONE.

Professor Hughes, the inventor of the type printing apparatus which goes by his name, has added another to the multiplying marvels of contemporary science. To the telephone and the phonograph, he has added the microphone. In some respect it approximates the Tyndallean sound that "carries" to the ear, and causes to sound in the same way that selenium is sensitive to light. That is to say, if we place three bodies in the circuit of a small battery and subject them to sound vibrations of other words, talk at them—the electric current is modified, producing through it will be so continuously modified as the voice that the object may be used instead of a telephone for sending a message.

In the last number of *Nature*, from which the above paragraph is extracted, Professor Hughes's little instrument is described at some length, in connection with experiments given by him before the Royal Society. He used a battery of three simple Bunsen's cells, and a telephone as a phenomenon of the present character. At first he used a stretched wire, but, thought that the vibrations talked at, no effect was marked until a breaking strain was applied; at the moment of breaking a sound was heard. Next the broken ends were pressed together. But in Professor Hughes's own words:

It was soon found that it was not at all necessary to join two wires endways together to reproduce sounds. Two pieces of wire placed vertically one on the other would do as well when their surfaces were in contact, and no matter how considerable a resistance to the current existed at the point where the contact was made, whether one or more portions of the electrical conductor were in the form of loose powder, or of a contact, by a slight pressure between them, sound could be heard. Wire terminals in two communicating circuits, one of platinum and the other of silver by a slight pressure, were exceedingly feeble, and by laying a similar pair between them, sound could be heard. Even when the platinum terminals were left lying on the table by their own weight, that a square coal—flannel on, using two of the latter, and by placing a sound plate on the vibrations were almost produced, the effect increased with the weight. Even when the surface of the wires was wanting, as in the following experiments the Geiger because more and more sensitive, such as water powder—a platinum, and nothing to be detected. Several other metallic powders also metallic filings, placed at the points of contact, greatly added to the power of the instrument.

The Professor found that the material with the materials used. "All metals, however," says Professor Hughes, "could be made to possess this property, provided the division of the metal was sufficiently great, and that the material used does not oxidize by contact with the air during the experiments. Thus platinum and mercury are very sensitive and answering in their results, while lead soon becomes of such high resistance as to render communication upon the surface as to be unsatisfactory. A mass of height round about is peculiarly sensitive to sound, while clean, but as the skin soon becomes coated with oxide the sensitiveness ceases. Carbon, made from its surface being entirely free from contraction, is excellent, but the best results I have been able to obtain at present have been from mercury in a finely divided state. I took a comparatively porous conducting body, such as fine willow charcoal used by artists for sketching, heating it gradually on a white heat and then dipping it into mercury while it is incandescent. The mercury in the pores, caused by the sudden cooling, becomes fixed with innumerable minute globules of mercury, thus, as it were, isolating the mercury in a fine state of division. Some of the charcoal carbon treated in a similar manner with and without platinum deposited upon it, and the chloride of platinum, I have also found similar effects from the willow charcoal, heated in an atmosphere of hydrogen, to a white heat and containing a few particles of silver or silver easily reproduced metal. Under certain conditions, the willow carbon will be found to be metallized, having the metal distributed throughout its pores in a fine state of division. Iron also seems to enter the pores if heated to a white heat without being exposed to air, combined with the carbon, as in graphite, and, indeed, some of the best results have been obtained from what I call physical conducting pow ts a fine state of division."

This extension is a question well worth, as we have said, considering at a length, and is called a transmitter. The resistance of the conductors employed is effected by a substance absolutely invisible, and it is this quality which Professor Hughes utilizes in what he calls, par excellence, his microphone. This marvelous instrument, of which we shall here so much in the future, consists of a box-shaped pieces of gas-carbon, one inch long, one-quarter inch wide at the centre, and one-eighth inch thick; the upper pointed and plays free in another carbon block. The two pieces of carbon are connected in metallic, and a battery is used in preference to any other material, since it is more reliable and reliable. Of an instrument this character Professor Hughes, the inventor, says:

The best form of carbon materials for this instrument, however, have not, as yet, been fully experimented on; still, in its present shape, it is very sensitive, and for ordinary purposes is quite in reference. If a microphone is required to be used for a long time, a battery of two cells is sufficient. With this arrangement, I can hear the fly walking quite distinctly. The tick of an ordinary watch can be heard at least a hundred miles distant from the source of sound. In fact, when fairly started on the subject, I find that there is no limit to the sensitiveness required in this result, what has hitherto escaped us with-matter too small for human vision.

When a fly's tread can be heard 300 miles away miracles become possible. Our own day has seen the annihilation of obstacles in the matter of time and astronomical chronology is now a recognized branch of science. But a step we not since day has announced that Mary's-be able to detect the presence of life on another planet by distinguishing phases at least? Our syntactic sense has already done wonders, and we may expect it to do wonders are better up than it has yet done. The microphone was peculiarly fitted for physiological researches. What may we expect in its ab ove unfilled a sphere but the sounds which the functions of living bodies in health and disease give out—even when these sounds are entirely inaudible by ordinary means? The trend of science on the advance, the approach to truths—indeed, of all moving bodies; counting any sounds, may easily and surely be detected by the microphone. Light has long enjoyed a monopoly of scientific attention, but the new scientific inventions were for ordinary light and sight, for making improvements in optical instruments. Now that we have turned our attention to the ear and sound, our marvels have already been startling and wonderful. But new conquests are before them. Touch, taste and smell are yet almost untouched. They have never yet received the attention they deserved. Perhaps when they do, as great results await scientific research as have already rewarded it when devoted to sight and sound.

STAR COURSE ENTERTAINMENTS

NINTH SEASON—EIGHTEENTH SERIES.

This Monday Evening, April 15th, 1878,

Professor GEORGE F. BARKER,

(Of the University of Pennsylvania.)

SUBJECT,—"THE TELEPHONE."

SYNOPSIS OF THE LECTURE.

SOUND.

Form of the sound-wave in air; Velocity of transmission of these waves; The pitch is higher as the wave is shorter; Audible sounds usually transmit sound; Lovers' Telegraph; Vibration of membranes by sound-waves; Reproduction of these waves. Phonograph.

ELECTRICITY.

Field of force which surrounds a magnet; Use of magnetic needle to detect currents; Magnetism produced by electricity; Electro-magnet; Electricity produced by magnets; Character of magneto-induction currents; Transmission and reception of electric waves.

APPLICATION.

Telephone, an electric apparatus for producing sound at a distance; First telephones transmitted music, Reis, 1860; Harmonic telephone and telegraph of Gray, 1873; Speaking telephones first constructed in 1875; Reiff's telephone at the Centennial Exhibition; Magneto-telephone of Dolbear, 1876; Various forms of magneto-telephones in use; Edison's carbon telephone of 1877.

DEMONSTRATION.

Reception of articulate speech by telephone; Reception of music from various points by means of musical telephone.

CHAS. J. GRAF, Teacher of Piano, Reference: T. B. Pugh, No. 927 Chestnut Street, Prof. Wm. G. Fischer, No. 1316 Chestnut Street.

☞The Piano-Forte used by the Star Course are the well-renowned STEINWAY Instruments, CHAS. BLASIUS, Agent, No. 1006 Chestnut Street.

VISITORS ARE ALWAYS WELCOME AT

THE Bryant & Stratton

BUSINESS COLLEGE.

ASSEMBLY BUILDINGS, 708 SOUTH TENTH STREET.

In order to make the course of Instruction in this Institution in every way practicable there is in constant operation a Bank, Commission House, Importing and Jobbing House, Railroad and Steamboat Offices. The students fill all the positions in the various departments of the business. Students can enter at any time. Open day and evening. The "RESERVE CASE" and Illustrated Circulars sent free.

J. E. SOULÉ, Principal.

THE ILLUSTRATED
ADELAIDE NEWS

ADELAIDE: FEBRUARY, 1878.

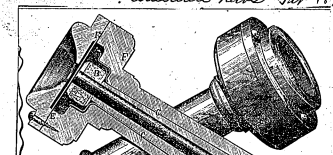
THE TELEPHONE.

This wonderful little instrument (invented by Professor Bell), by which the sound of the human voice is conveyed to a great distance, and which has recently caused so much excitement in Europe and America, was successfully introduced to the Continent of South Australia last November. To the colony of South Australia belongs the honour of bringing it before the public in the Antipodes, and to Mr. A. W. Dobbin is due the credit of being its first manufacturer and introducer. The accompanying engraving, in which both sectional and exterior views of the instrument are given, will give our readers a very correct and intelligent idea of the construction of the telephone as made by Mr. Dobbin. Referring to the sectional view, A is permanent magnet, held in position by the adjusting screw in the rear. Around one end of the magnet is wound a coil (B) of fine insulated copper wire (silk covered), the ends of which are attached to the larger wires (C), which extend to the rear, and terminate in the binding screws (D). In front of the pole and coil (B) is a soft iron disc (E and F). The whole is encased in a wooden casing, having an aperture in front of the disc, and which, besides serving to protect the magnet, &c., acts somewhat as a resonator. The principle of the apparatus may be briefly enumerated as follows:—The influence of the magnet induces all around it a magnetic field, and the iron diaphragm (E) is attracted towards the pole of the magnet. Any alteration in the normal condition of the diaphragm produces an alteration in the magnetic field, by strengthening or weakening it, and any such alteration of the magnetic field causes the induction of a current of electricity in the coil B. The strength of this induced current is dependent on the amplitude and rate of vibration of the disc, and these depend in turn upon the air disturbance made by the voice in speaking, or in any other similar source. Therefore, first, a wave of air throws the diaphragm into a state of vibration; second, each movement produces a change in the magnetic field; and, third, an induced current is generated in the coil wire. Now if to the binding screws wires be attached, connecting in like manner with an apparatus precisely similar to that described, it will be clear that there will be a closed circuit of wire, and the induced current will pass along the wire and through the second telephone and back again to the first one; but in passing through the coil in telephone No. 2 it modifies the magnetization of the magnet and increases or diminishes its power of attraction for the diaphragm. Hence every vibration made by the first disc is repeated by the second one, and whatever sound produces the vibration of one is transmitted and reproduced by the other. If the telephone is being used for long distances one of the wires may be dispensed with by simply connecting one of the screws (D) on each telephone with a wire leading to the ground; by this means an ordinary telegraph line may be at once utilized.

Since Mr. Dobbin first introduced the telephone (last December) he has on several occasions entertained a number of ladies and scientific gentlemen and members of the Press with a series of most interesting telephonic experiments with the most happy results. Having had the pleasure of being present at one of these series we will give a brief outline of the proceedings. The experiments commenced by ladies and gentlemen carrying on conversation through a mass of insulated coiled wire, over a mile in length, one end of the wire being in the drawing-room and the other in the grounds at the bottom of the garden, two, and sometimes three, telephones being attached to each coil of the wire, so that several persons could listen and take part in the conversation at the same time. Every syllable uttered even in a very low tone of voice was heard distinctly at the other end of the wire, and sometimes even casual remarks uttered by other persons in the vicinity of the telephones were heard at the opposite end, which of course intensified the astonishment of those present. A number of songs and Sunday-school pieces were then sung at one end, which came through, if possible, with even greater distinctness than the speaking, the singing having a beautiful mellow tone, similar to that of singing in the water in the open air on a still, calm evening. When duets were sung both voices blended harmoniously together, and yet each voice could be distinctly heard. The telephone was next attached to the piano, and we were surprised at the distinctness with which every note was transmitted along the single wire. A musical box was now attached to the telephone, the effect of which was even more astonishing than that of the piano. A few other experiments were made, but the above is quite sufficient to give our readers a fair idea of the capabilities of the telephone. We noticed also that when Mr. Dobbin doubled the length of the wire that it made no difference whatever in the transmission of the sounds, which only confirms our Professor Bell's statements, that distance up to a certain limit makes no difference.

C. Todd, Esq., C.M.G., Postmaster-General, has also been very successful in conducting a series of experiments with the telephone, having transmitted songs and conversations along the telegraph line between Adelaide and Kapunda, a distance of 43 miles.

By the *Illustrated London News* of December 15, 1877, we notice that conversations have been carried on through resistance coils equivalent to 6,000 miles; but the longest line of actual distance through which conversations have been successfully carried on is between Boston and New York, a distance of 238 miles.



Thomas Edison and the Phonograph.

We take occasion in this week's Paper to inform our readers of the recent advances which have been made in the mechanical transmission and recording of vocal sounds. Upon the following page may be found an account of the development of the telephone. Our task at this moment is to describe a still more startling achievement of genius, and that is a successful record and reproduction of human speech by a simple machine, called the phonograph. We shall speak first of the man who has accomplished the achievement, and second of the machine itself.

In 1847 Thomas Edison was born in Ohio. When he was eight years of age his parents moved to Michigan, and young Edison began life as a newsboy. He was a driving newsboy. At 15 years of age he obtained a contract for the exclusive sale of newspapers on one of the largest Canadian railways, and had a squad of boys working under him. While he was still running on the trains he began chemical studies, fitting up a traveling laboratory to take with him on the cars. Then he became a telegraph operator, and soon afterwards stood at the head of the craft. He celebrated his 20th year by conceiving the idea of sending two messages over the same wire at the same time, thus doubling the capacity of all previous systems of telegraphy. For the last ten years he has pursued his electrical studies and inventions, working with surprising swiftness and exceeding zeal, until to-day he has succeeded in recording and reproducing the human voice and won a world-wide fame.

The phonograph is regarded as the greatest triumph of inventive genius which has been attained even in this inventive age. It is greatest in its achievement and peerless in its simplicity. The engraving on the page shows at a glance the principles upon which it operates. It consists of a hollow cylinder, *A*, mounted on a horizontal screw, the cylinder being rotated and at the same time moved laterally by turning a crank at the end of its shaft. The chief part of the apparatus is the diaphragm, marked *B* in Fig. 1, and shown in detail of its parts in Fig. 2. At *C* is shown the thin plate of metal held by its edges, so that it can vibrate, and at *D* is a fine needle or stylus, which is attached to the

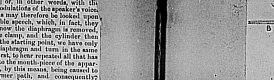


Fig. 1.

Fig. 2.

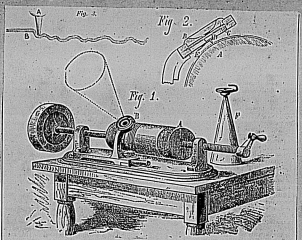
center of the diaphragm. The cylinder is covered with tin-foil, and the diaphragm, *B*, securely fastened in place by clamping its support to the base of the instrument. When this machine is properly adjusted, the stylus, *D*, should lightly press against that part of the foil over the groove. The crank is now turned, while, at the same time, someone speaks into the mouth-piece of the instrument, which will cause the diaphragm to vibrate, and as the vibrations of the latter correspond with the movements of the air undercompression, the soft and yielding foil will become marked, tracing the line of the groove by a series of indentations of different depths (Fig. 3), varying with the amplitude of the vibrations of the diaphragm; or, in other words, with the inflections and modulations of the speaker's voice. These inflections may therefore be looked upon as a sort of visible speech which, in fact, they really are. If now the diaphragm is removed by loosening the clamp, and the cylinder then turned back to the starting point, it is easy to replace the diaphragm and turn it in the same direction as at first, to bear repeated all the words been spoken into the mouth-piece of the apparatus; the stylus, by this means, being caused to traverse the former path, and consequently rising and falling with the depressions in the foil, its motion is communicated to the diaphragm, and thence through the intervening air to the ear, where the sensation of sound is produced.

The method in which the stylus indents the tin-foil is shown in magnified form in Fig. 3, at being the stylus and *B* the cross-section of the tin-foil. In reality the marks left by the stylus are very fine, as the sheet of tin-foil is taken from the cylinder it is grooved with parallel lines about 1-4 to the inch. In each groove there are the indentations of the stylus, quite regular as to size to the naked eye and about 50 of them to the inch.

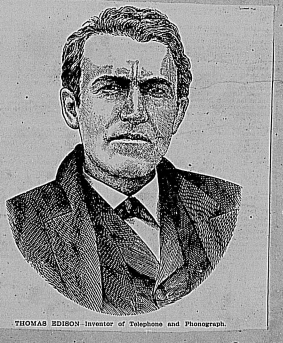
The Phonograph at the Grand Musical Festival.

The phonograph admits of many applications. The tin-foil sheet bearing the recorded speech in one place may be taken from the cylinder and sent thousands of miles, and being placed in another phonograph will reproduce the words and the tones of voice originally imparted to it. This will probably be fully shown at the coming Musical Festival in this city. For some time past Manager Bigelow has been endeavoring to secure a phonograph for the purpose of giving a public exhibition of its wonderful performances at the first day of the Festival. Samuel Hubbard, the agent in this city, has received a dispatch stating that the phonograph will be promptly forwarded—also the tin-foil impressions of warblings by Miss Kellogg, Miss Aus or Rudersdorff and a greeting from Rev. Henry Ward Beecher, for the purpose of reproducing them through the aid of the phonograph at the Festival. Carl Zerrahn, the director, is provided with his tin-foil impression of "Yankee Doodle."

In an article in *North American Review* Mr. Edison indicates what are its probable applications. We may expect before a year is ended to have it rendered commercially serviceable. The principle can be applied to every implement or toy which makes a noise. Think of each new speak the hours, instead of striking them. A child's doll sent Christmas day may repeat the moral precepts which we now put in children's copy-books. The locomotive approaching a crossing may screech out: "Look out for the engine!" or it may cry out the name of the station it is approaching. Mr. Edison believes he can intensify sounds as well as reproduce them as they are committed to the instrument. He says that he can in time make his machine talk so loudly that it can be used on vessels to warn off other ships during fogs. Another last astonishing proposal is that he shall build a huge phonograph to go in the great torch of Liberty which is to be erected in New York harbor, so that the metal giant can make a voice audible over the entire bay. In view of what Mr. Edison has already accomplished, his success in this respect would not surprise us.



THE PHONOGRAPH WITH SECTIONAL VIEW OF DIAPHRAGM.



THOMAS EDISON—Inventor of Telephone and Phonograph.

Concluded on next Page

The Speaking Telephone.

Great progress has been made in the introduction and application of the telephone to the practical uses of intercourse and communication since we gave a description of the Bell instrument seven months ago. The workings of the instruments have been improved, and great advances have been made in methods of making them useful. Other inventors have brought out telephones which are coming into wide popularity because of their excellent qualities.

We show upon this page engravings of two telephones. One is the invention of Thomas Edison, who has achieved widest fame by his phonograph, which we expect soon to illustrate and describe. One of the main features of the Edison telephone is the employment of a carbon disk for the purpose of varying the strength of a battery current in unison with the rise and fall of the vocal utterance. He found that by vibrating a diaphragm with varying degrees of pressure against a disk of carbon, which is made to form a portion of an electric circuit, the resistance of the disk would vary in precise accordance with the degrees of pressure, and consequently a proportionate variation would be occasioned in the strength of the current. The latter would thus possess all the characteristics of sound waves, and by its reaction through the medium of an electric magnet, might then transfer them to a metallic diaphragm, causing the latter to vibrate, and thus produce audible sounds. (Photo-engraving, which is copied from the lately given by *Scribner's Monthly*, shows the arrangement of the parts of the transmitting apparatus of the Edison telephone. The carbon disk, *a*, is inserted by the back portion, *f*, over the diaphragm, *d*, and placed between the two platinum plates, *b* and *c*, which are connected in the battery current as shown by the lines. A small piece of rubber tubing, *h*, is attached to the center of the metallic diaphragm, and presses lightly against an ivory piece, *e*, which is placed directly over one of the platinum plates. Whenever, therefore, any motion is given to the diaphragm it is immediately followed by a corresponding pressure upon the carbon and by a change of resistance in the latter, as described above. It is obvious that any disturbance properly fitted with an iron diaphragm, will answer for a receiving instrument in connection with this apparatus.

Another telephone which is coming into wide use, is that invented by Mr. A. G. Phelps. The peculiar excellence of Mr. Phelps's instrument is said to consist in its distinct articulation, combined with a loudness of utterance that is not to be found in the many other forms which have been thus far brought forward. The instrument designed by Mr. Phelps is shown in our engraving. It consists of a polished case of hard rubber or rosewood with magnet, coils and diaphragm inside. In connection with this telephone there is used a small electro-magnetic machine, contained in an oblong box, which is used as a call bell when the attention of a distant station is required. The currents which are produced by this machine by turning a crank, are discharged by the connecting wire through the bottom of a polished magnet, coiled, and causes a hammer attached to an armature lever to vibrate violently to and fro, thus producing a violent ringing, audible at a distance of fully forward at a considerable distance from the machine. The points of description, which we have taken mainly from *Scribner's*, will be noticed on the subject, are of particular interest, because of the great numbers of this style of telephone which are being introduced in this city.

The use of the telephone in this city has been marked by the character of enterprise which usually attends the introduction of progressive inventions amongour wide-awake people. The American District Telegraph Co. have furnished a large number of the instruments to private parties, and they have given the use of the telephone features which were original with them, but which from their plain advantages are now being introduced in other cities. Notable is the arrangement called the "central system," at their establishment on Newsome street, near California, they have a telephonic office, presided over by the management of Mr. Sabin. In this room each wire from the distributed subscribers centers. If the owner of a telephone wishes to communicate with another owner in any part of the city he signals or calls the central office, and the wire is connected with that of the other party. There are now 100 firms connecting in this office and each one can then, at a moment's notice, put in communication with any one of the 99 others. Thus any firm can communicate with another as easily as it would speak with men, as the messages pass direct without even the intervention of the operator. When a firm is called from the central office they are told the name of the party who addresses them by the central operator, so there would be no chance for the telephonees to impress on one another by calling names. Each firm is furnished with a schedule of all the others which are in communication with the central office. As we have said, the smallest advantage of this centering idea is so great that the great cities at the East are thinking of following the example set them by the enterprising company in San Francisco.

Our coast is kept well abreast of the progress in the adaptation of electro-magnetism to common uses by our skillful friends which makes a specialty of this branch of work. Besides the above, the District Telegraph Company which we have mentioned, there is the California Electric Works which is cognate in its sphere. The gentlemen in charge of this company are second to none in the country in their peculiar profession. In the application of important discoveries abroad and in original discovery and invention they are wide-awake and successful.

A VISIT TO EDISON.

How the Great Inventor Lives and Works.

Anecdotes Characteristic of the Man.

Bits of Gossip Gleaned in a Globe Reporter's Visit.

Last Tuesday the representatives of the daily press of Boston and other positions started on a very pleasant excursion to Menlo Park, New Jersey, in which place the home and laboratory of Thomas Alva Edison, the famous inventor, are situated. Menlo Park, or "Pallasville," as it is sometimes called, is twenty-one miles from Jersey City by the Pennsylvania Railroad, and by the courtesy of the Pennsylvania Railroad, each guest was an elevated site commanding a magnificent view of the surrounding country. The party was under the charge of Mr. Edison, who, in his private car, with his turnout while carrying out lunch, which, when partly eaten, was passed around from hand to hand of course. The party left Boston by the Fall River boat on Monday evening, and arrived at Jersey City at 8:30 the following morning. Mr. William Hallidan, the manager of the Boston branch of the American District Telegraph Company, was in charge of the party, and from the very beginning of the trip to the time of the separation at Jersey City, he was the recipient of the thanks of the entire party for his untiring zeal and care. Every one was accommodated, and every minute detail, even, which could add to the pleasure and comfort of the party was punctiliously, politely and pleasantly attended to. The party was met at the depot in New York by Mr. Edison's private car, by Mr. Edward H. Johnson, the General Agent of the Phonograph Company, and by Mr. Norvin Green, the head of the Western Union, and by his secretary, who is also the phonograph business and gentlemanly beating.

Upon the arrival of the party at Menlo Park, the officers of the Edison Ore and Stone and the Fall River boat put forth every possible effort to make the guests of the company feel at home, and the warm commendation of all present for the hospitality shown by the officers of the company was certainly a subject of remark. A few anecdotes characteristic of the eccentric genius are given as follows:

Absent-Minded Edison.

In a conversation with Mr. Thomas Rocks, Manager of the Edison Electric Light Company's office in this city, and Mr. D. J. Hayes, an operator in the Western Union office, who is also a guest of Mr. Edison's, a Globe representative gleaned the following items of interest. Mr. Rocks said: "Edison is one of the most absent-minded men I ever came across. He often calls with a little ruler in his hand, and, holding it in a very peculiar way, and with the middle finger of his right hand, and, in the course of conversation, will suddenly bring the ruler down on a bottom, impressed upon every one present, 'I've got you at last, Tom!' Well, if I should pass but one word to him, he would say, 'Tom, I've got you at last!' Or, if I should say, 'Good morning, Mr. Edison,' he would say, 'Tom, I've got you at last!' Of course, I begged him in the name of all the powers to tell me what he meant by such words. He explained, and, placing it in his pocket, said that he had intended to have it engraved, but that it was a present from a friend of his in New York, and that he always carried it with him. He also said that he had promised to be accepting," said Mr. Rocks, "by the brother operators. He was a first-class operator, and was employed in the Western Union office. He was a poor speller, however, and was always the butt of the fellows' sarcasm." These remarks of Mr. Rocks were fully corroborated by Mr. Hayes, who said Edison was always honest enough to acknowledge that he was a poor speller.

He Was Always Kind.

Generous and open-hearted, never refused to assist an applicant, whether he knew him or not. He (Mr. Hayes) remembers that two of his fellow-men, who were out of employment, came into the office where he was working and stated their cases to him. Edison did everything a man could do for them. He let them room with him, and, I believe, furnished them with food, etc. Several days elapsed, and they still "stuck" to the phonograph. At this point Edison became impatient, and Mr. Rocks took up the thread: "Come on, friends of Edison's," said he, "we're idle. Let us go and get employment." Edison, however, objected, saying his hospitality I last Edison felt my duty morning seeking employment. I remember one time in the convention when he demonstrated of the men. When Edison first came to Boston he was a very complacent and modest man.

He Got 'Struck'

away up near the skies, and came to Boston by a circuitous route, wandered into the Adams House, the corner of Court and Tremont, and purchased a nice tall hat. Of course you can imagine, from the above description, that Edison is a tall man. Of course you can imagine, too, that he looked very much out of place in such a hat, and that when he appeared on the street he was simply sidesplitting

A Very Modest man is the office, and was never afraid of work. He used to say every time some one was making an appearance, "I shall be all the very little, and ask for nothing." He was always at his post, and was never known to be late. He was always "there next to no man manner intelligent, whom we have ever met. He was a good writer, and could write very rapid indeed. He could write from seven to eight hundred words per hour. He was also a very rapid reader, and his memory was wonderful. He could read a column of matter at a glance, and then repeat it word for word

THE OPERATOR
A JOURNAL OF Electric Practical Science
June 1st, 1878.

Thomas Alva Edison.

Edison started a shop in Boston, and gave all his spare time to it. His ideas here began to assume practical shape. He invented a fire alarm system for private line use, and put several into practical operation. He made a chemical vote-recording apparatus, but failed to get it adopted by a Massachusetts legislature. He commenced his experiments on duplex telegraph apparatus, and made trial tests between Boston and Portland. He matured his first duplex line printer, and put eight into practical operation. From lack of money to pay for operatives, his venture was not successful, and he sold out. The patent subsequently came into possession of the Gold and Stock Telegraph Company, and was considered to have a large and valuable value upon which many subsequent improvements were built.

At one time he was on the trail to explode the operation of the telegraph, so that he supposed was a girl's school. The forged letter, appointment, and when found, was putting up a line on a house-top. He went directly from the letter and was brought aloshed or fled himself subject to the presence of a room full of finely dressed young ladies. He was actually timid in ladies' presence, but his subject was understood, and the occasion passed pleasantly. He was introduced as a member of the young ladies, who always recognized him on the street, with the consciousness of his fellowship with which he is honored. Edison has a strong believer in the future girl.

His idea of a duplex system constantly burned in his brain, and in 1870 he went to Rochester, N. Y., to try his apparatus between the two cities. Mr. F. O. Pope, then assistant superintendent of the Western Union Telegraph Company, assisted in New York. The effort was a failure, although Edison has always claimed it ought to have succeeded. He then went to New York, arriving there dead broke and disconsolate. He first went into the office of the Gold Indicator Company for several days. Their apparatus was constantly out of order. At such times Edison would be called and manual instrument repairs. One day when there was an unusual excitement in the gold market, the operators failed. The superintendent of the Gold Indicator office was great. The superintendent of the Gold Indicator office was great. The superintendent of the Gold Indicator office was great

SALEM, OREGON, MAY 31, 1878.

PUBLIC SPEAKING.

J. J. Whitney, Democratic candidate for District Attorney of the Third Judicial District, will speak on the political issues of the day at the following times and places, to-wit:

Corvallis, Tuesday, May 28, at 1 p. m.
Silverton, Wednesday, May 29, at 1 p. m.
Salem, Thursday, May 30, at 7½ p. m.
Stayton, Friday, May 31, at 7 p. m.
Jefferson, Saturday, May 32, at 1 p. m.
Scio, Monday, May 27, at 1 p. m.
Lebanon, Tuesday, May 28, at 1 p. m.
Brownsville, Wednesday, May 29, at 1 p. m.
Harrisburg, Thursday, May 30, at 1 p. m.
Albany, Friday, May 31, at 7½ p. m.

The Telephone in Salem.

Mr. J. H. Strong of this city, agent for the American Telephone Company, has obtained some of these wonderful instruments, and now has them working at his house. We had the pleasure of trying the practical workings of them and can only say they are all that is claimed for them. One can hear by help feeling the seeming ridiculousness of talking to a little wooden instrument which he holds to his mouth, but when he holds it to his ear and hears the reply as distinctly as though seated by the person who is talking, he can not help acknowledging that the telephone is the greatest discovery since Morse found a method of making the electric fluid a medium of communication, and the useful purposes of man. The present telephone is probably only a beginning of the wonders which are to be accomplished by the discovery of the possibility of transmitting sound, and we can see scarcely realize the broad field of usefulness to which it is destined. There can hardly be a limit to its application. Mr. Strong and others contemplate the erection of a line of wires from this city to Dallas to be used for conveying messages with the aid of the telephone, and there can be little doubt that it will prove a profitable investment. In a very short time every town, and hamlet in the State will probably be connected with the more important cities and towns, telephones and the facilities this affords to business can scarcely be calculated. In order that all persons in the city may learn the working and uses of this great invention, Messrs. Strong and Cooper will give a public exhibition of it at Reed's Opera House. Connection will be made with the telegraph company's wires, and the audience will have the privilege of conversing with persons at the various points in this State where telephones have been obtained. Mr. Strong will also deliver a lecture on the subject of the telephone and electricity which will no doubt be very interesting, as Mr. S. is one of the best electricians in the State, having made this matter a study for many years.

Boston Courier.

SUNDAY MORNING, JUNE 2, 1878.

Mr. Thomas A. Edison's inventions are likely to work an important revolution in the business of society—especially in the accounting department, as witness—

THE CURRENT REBUKED.

When thieves came with light the gear
This system set to place,
For still the first thing they saw
I knew my telephone.
Through closet door from then I saw,
Or from the kitchen room
I gave the alarm,
And though many ten thousand miles,
Or from the Rocky Mountains,
Yet I can hear and speak,
And oh, unless fresh burglar beguiles,
Upsetting with new trickery,
I'll warn the thoroughfare.
Yes, I'll be faithful as a watchdog,
Here facing each door, jealous doubt,
I'll call once all my ears,
And though I have no eye I'll bet,
Ears of the best, by telephone,
My letter-hair by phonograph,
My sons, my uncle!

NEW YORK, FRIDAY, MAY 31, 1878.

THE HERALD will be sent to the audience of

PHONOGRAPH AND TELEPHONE.

PROFESSOR EDISON EXHIBITS HIS INVENTIONS AT ST. VINCENT.

A pleasant reception, consisting of an exhibition of the phonograph and telephone, was given last evening at the residence of the secretary and of the Academy of Music, St. Vincent, to the Hudson. Professor Edison was present and explained the working through he did not explain, as have previous ones, in the audience on one side of the room, and the ladies and their gallants, capable of the accession to the number of nearly two hundred. The chairs on the other side of the hall were occupied mainly by ladies and gentlemen, the friends of the pupils and their instructors. Before forty or fifty minutes filled a high, narrow, gallery, extending across the rear wall. Amongst among the guests were Miss Clara Morris, the actress, and her husband, Mr. Harriott; Mr. Gilbert Vintner, Mr. Barnum's wife; Very Rev. Michael Lilly, D. P.; Very Rev. James Shearer, Rev. L. Kinsel, late chaplain at the academy; Rev. C. Tracey, Edmund B. F. Arnold, of Newport; Thomas Kinsel, M. C. Thornton, E. F. Lacey, William Sedden and Ignatius F. Dandolph. Quite a large party of ladies and gentlemen visited the city were present, the remainder being chiefly from the village itself and the neighboring cities of Yonkers.

The entertainment was opened with a piano solo by Miss Josephine Sullivan, of Yonkers, which piece was then rendered by Mr. H. J. Tinsdell, a lawyer in this city. After explaining briefly the new telephone and phonograph, Professor Edison said he was very glad pleasure in exhibiting them to the audience, as the latter might be pay, in the near future, we may have them generally in use. New York lawyer could now plead a case in Chicago. It would be unnecessary for him to be present in person to make a successful argument, as he could be heard as well as if he were present in person. The instrument then would act as one of the counsel. The speaker then went on to say that the phonograph would be of great service to the deaf and dumb, as they could hear and speak by its aid. Professor Edison then explained the working of the telephone, which will no doubt be very interesting to the public when the instrument is brought into general use. He said that Colonel Waite had at Washington a telephone which he used for practical business of the Government. Some five years or twenty minutes were occupied by the delivery of a message from Washington to Boston, and he expected by the assistance of the phonograph to send a message day, and remember his business further enough to transmit it by the telephone. Then he mentioned several uses of the instrument.

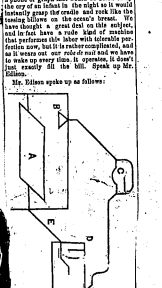
THE NATURE OF THE PHONOGRAPH.

A few words were then said as to the nature of the sound was arranged for him as to the working of the phone and phonograph, the latter being loosely described as a machine for recording sounds and reproducing them at pleasure. The speaker then proceeded to explain the working of the phonograph, which is too technical for the general reader to understand. Suffice it to say that the sounds are recorded on tinfoil, and reproduced by the passing of a needle point over the indentations made in the foil. The needle point is connected with the diaphragm of the instrument, which is made to vibrate by the passing of the needle point over the indentations, and thus reproduces the sounds. He also explained the working of the telephone

Among the slips in the book prepared by Mr. Tower for the occasion were contributions and his answer. The puzzle was propounded by THE BOOKMAN HAWKERS, and is as follows:

Candid Mr. Edison invent some kind of a phone or graph that would be acted on by the cry of an infant in the night so it would instantly grasp the cradle and rock like the tossing billows on the sea of dreams. We have thought a great deal on this subject, and in fact have made a crude kind of machine that gratifies us the labor with tolerable purity now, but it is rather complicated, and as it wears out *our cradle* will soon have to wake up every time. It operates, it does't just exactly fill the bill. Speak up Mr. Edison.

Mr. Edison spoke up as follows:



A. Cradle.
B. Telephone.
C. Battery.
D. Box containing parrots and cockatoos with liver.
E. Which moves the cradle.

The baby's office was received by the telephone, which, operating through the battery and magnets, set in motion the lever which rocks the cradle. When the baby stops crying the cradle ceases to rock.

After this there was nothing left for the guests to do, and this they did at their leisure. Mr. Edison having disappeared as they entered their way to the railroad station.

N. B., agents wanted. No hucksters need apply.

PROFESSOR HENRY ALBERT AN ACTOR.

THE LATE SECRETARY OF THE SMITHSONIAN INSTITUTION ON THE STAGE.

Thurlow Weed in New York Tribune.

I was alike gratified and relieved by the letter in this morning's Tribune, recently written by Professor Henry to Mr. Patterson. I had fears that Professor Henry, like many eminent scientists, had drifted away from his early religious moorings. The letter reassuring with much clearness of perception, and with such a wealth of illustration, the power, wisdom and goodness of One, by whom all things were created, and by whom preeminence animate and inanimate, nature is harmonized and unified, is, therefore, a gratification and a relief. While Professor Henry's letter is addressed to me, my esteemed friend, Robert C. Winthrop, of Boston, called. He had just read and was much pleased with the letter. Mr. Winthrop had known Professor Henry long and intimately. Being in Washington recently and hearing of his friend's illness, Mr. Winthrop called upon him. The professor explained the nature of his illness, (a partial "paralysis of his right hand and arm), but expressed a confident belief that he would be able to make his annual tour of observation along the coast in a small vessel which the government provided for him. In the course of their conversation the lamentable theory was spoken of.

Mr. Henry remarked that novel and bold theories, even if fallacious, were productive of good, because in the research and discussion which succeeded the facts and arguments adduced to expose error were also to confirm and establish the truth.

In the sketches of the life of Professor Henry an incident is omitted, perhaps, because none but myself are known to relate it. As that incident gave to the professor one of his most distinguished ornaments, it seems worth relating. My acquaintance with Joseph Henry, commenced in Albany, ripened into a warm friendship. He was then an apprentice to John F. Dove, a silversmith in State street, Albany. I was a journeyman in the office of *The Albany Argus*, published by Henry C. Southwick, and edited by Solomon Southwick. During the war with England, which had just closed, the Green street theatre, with a strong company, liberally patronized by the officers of the army stationed in Greenbush, awakened much enthusiasm among the young gentlemen of Albany, several of whom formed themselves into an amateur theatrical company. They fitted up a hall formerly used as a dancing academy, then known as the "Bunghole hotel, on the corner of North Pearl and Hamilton streets. They selected large auditorium. Joseph Henry became a "bright particular star." Miss Young, *Harriet, Duncan* and others, "Cato," were announced equal in conception and execution to the pretensions of experienced and popular actors. His friends, appreciating his talents and genius, urged him to adopt the stage as a profession. His own thoughts and inclination rendered him a willing listener. Soon the manager of the Green street theatre offered him a permanent engagement with a liberal salary. With that the young aspirant for dramatic honors was greatly delighted. But Dr. T. Romeyn Beck, principal of the Albany academy, believed that there was a way opened to the young man promising greater usefulness and more enduring honors than the boards could confer. After consultation with the trustees, Dr. Beck invited young Henry to enter upon and complete a gratuitous academic course. While assiduously cultivating these confiding offers three of his intimate friends, James Dexter, a law student, James Hunter, a printer, and myself, were called into consultation. Hunter and myself sue for our friend in a dramatic career ensured fame and fortune. Dexter, less enthusiastic, preferred to look nearer to those of the "rock" and "bunghole." He urged, and but forcibly, that if the stage was to be ultimately adopted as a profession, an academic education would increase our friend's chances for enduring success, and would be something valuable to him he would have, quite young enough to become an actor. I was sanguine, after a long and anxious mental struggle, proved effectual. The following year Joseph Henry resigned Manager Dorlaska's dramatic offer, and took his seat in the Albany academy. Mr. Dorly, when informed of his apprentice's desire to become a student in the academy, generously surrendered his indenture. There was only a few weeks before the "Albany Routine" became so absorbed, in and delighted with his studies that the theater with all its attractive associations was forgotten. Long years afterward, when we met in Washington or in his office in Albany, while recalling the scenes of our youth, the grave Professor Henry, with a world-wide scientific reputation, reverted with epicurean delight to his life as partaking more of a dream than as a reality.

A STAGE TAVERN ROMANCE.

SATURDAY, MAY 4, 1878.

Electro- and Stereo-typing.

One of the most important industries which have originated during the past quarter of a century is that of electrotyping, when in at the same time the most useful, and now ubiquitous and in production of the most important before. When we consider, in this connective day, of works which pass through inventor's of editions, and the light of magazines, every year, a proportion, is no-ments, etc., which demand extensive reprints, we can form some idea of the value of this process, for at least the economical improvement in the time and labor required. The value lately to be "plated" in any concern, or to prevent disagreement, and the consequent expense. In the multiplication of the impressions of any work once it is stereotyped, as but for electrotype each out would necessarily have to be re-photo engraved, and before soon destroyed by the rollers of the printing press, he requires every again. Being desirous of ascertaining the progress made in this branch of industry, we lately paid a visit to the Electrotype house of this city, Messrs. Keeler, Rice & Co., No. 37 to 47 Vandewater street, where establishment we found to be the most complete and comprehensive in every department of any we have hitherto inspected. This house was established by Lovejoy & Wheeler, in 1870, in a very small way, personally inclined to a new enterprise, in White street. Business gradually increasing, however, a removal was made in 1876 to 19 Vandewater street, where it remained until this spring, when an opportunity offered for the acquirement of even a more peculiarly and admirably suited to the in-town than referred, by any other house in the country; the newly erected five-and stone-front of Mr. George Nugent, which reaches an elevation of over 103 feet above the level of the ground, is directly fronting the East Rivery and the new bridge, and covers, above all other buildings, commands a brilliant and unincumbered view. The establishment, consisting of the entire building, covers an area of 7,500 sq. feet, each department communicating one with the other by means of elevators, and is admirably adapted for the rapid and systematic execution of the business, and for safety and easy communication.

The New Establishment, familiar from the office, is the receiving room, in which respective agreements are made. In this department is also found a machine for applying, automatically, the plumb wash and sand to the back of the moulds, which are composed of wax, by which they become more durable, and from which the wax is poured in copper. Being battery they are then placed in the vats, and the deposit of copper. Being placed in the vats, and the deposit of copper. Being allowed to remain for two upwards, a volume of the liquid is thrown upon them, when set, rejected from these vats, which by the process is not injured, after which a brush, is always the case. We may remark that this is the only house, excepting Harper Bros., now using this machine. This process is termed "wax block-leading." This house was also the first to adopt the magnetic-dynamo machine, imported in the year, one and, from England, which is, how-ever, now replaced by improved machines of our own. In this connection, we may remark that no money or enterprise is spared in effecting every improvement in machinery. In this connection we may state that a machine shop is also on the premises, which is under the supervision of Mr. J. H. Ferguson, one of the firm, who is himself a practical machinist, by use of break-down, require are this readily made, in addition to which nearly all parts of the machinery are manufactured, so that no delay can ensue from breakdown

or other delay, which is a great desideratum of the facilities for a speedy execution of all work. The next department is the finishing room, which is admirably lighted on three sides, including North and East, which latter is of the highest and most peculiar importance. Adjoining this department are engines in use in course of erection, so that in case the one in engine should break down, the establishment can be never as if nothing had occurred. From this we enter the bronzing department, in which the improved machinery for placing and coating is in use. Here we have some 1,500 feet of moving or belt to be kept under thoroughly assessed, owing to the fine and the most powerful bronzed bronze. From this department we entered the electrotyping rooms, and the manipulations already mentioned. Some thirty hands are employed, many of whom have been connected with the house for over ten years, and are thus practically skilled in their var ous departments, and can be relied upon for honesty and faithfulness, a very important point in a business of this kind, and whereby the very finest work is always turned out. The house holds numerous patents for valuable processes, which in many instances save considerable the time of other methods, especially that of depositing copper through the agency of the electric battery. Two finish elevators and one passenger, and by contracting steam and water facility is secured throughout the extensive building. This, house was established in 1870 under the name of Lovejoy & Wheeler. In 1876 Mr. Wheeler retired, and the firm became Lovejoy & Son, Mr. R. W. Lovejoy purchasing Mr. Wheeler's interest. In 1876 Mr. J. H. Ferguson became associated under the present style, and in 1878 Mr. Keeler became a partner in the house. The members of the house are all experienced and practical men, of energetic, enterprising capability, with a letter is recommended from the fact that they are now doing a larger business than in the best times of '73 and '74. They do business for extensive publishers and printers, and to the public in general. Messrs. Keeler, Rice & Co., Vandewater street, whose name is mentioned until this spring, when an opportunity offered for the acquirement of even a more peculiarly and admirably suited to the in-town than referred, by any other house in the country; the newly erected five-and stone-front of Mr. George Nugent, which reaches an elevation of over 103 feet above the level of the ground, is directly fronting the East Rivery and the new bridge, and covers, above all other buildings, commands a brilliant and unincumbered view. The establishment, consisting of the entire building, covers an area of 7,500 sq. feet, each department communicating one with the other by means of elevators, and is admirably adapted for the rapid and systematic execution of the business, and for safety and easy communication.

The New Establishment, familiar from the office, is the receiving room, in which respective agreements are made. In this department is also found a machine for applying, automatically, the plumb wash and sand to the back of the moulds, which are composed of wax, by which they become more durable, and from which the wax is poured in copper. Being battery they are then placed in the vats, and the deposit of copper. Being allowed to remain for two upwards, a volume of the liquid is thrown upon them, when set, rejected from these vats, which by the process is not injured, after which a brush, is always the case. We may remark that this is the only house, excepting Harper Bros., now using this machine. This process is termed "wax block-leading." This house was also the first to adopt the magnetic-dynamo machine, imported in the year, one and, from England, which is, how-ever, now replaced by improved machines of our own. In this connection, we may remark that no money or enterprise is spared in effecting every improvement in machinery. In this connection we may state that a machine shop is also on the premises, which is under the supervision of Mr. J. H. Ferguson, one of the firm, who is himself a practical machinist, by use of break-down, require are this readily made, in addition to which nearly all parts of the machinery are manufactured, so that no delay can ensue from breakdown

THE DAILY GRAPHIC
WEDNESDAY, JUNE 5, 1878.

EARS FOR THE DEAF.

WHAT THE WIZARD OF MENLO PARK WILL DO NEXT—SURPRISING EXPERIMENTS.

It was evening room in the house of Mr. Edison's enthusiastic assistance and friend Clifford around Mount Morris Park, to witness the first trial, in the presence of witnesses, of the new ear trumpet which the inventor had evolved from his busier consciousness.

Mr. Edison revealed to Tim Dunning some two months ago, the fact that he was engaged in the construction of a "kindly susceptible ear trumpet, and our readers will recall the letter in which he invented, without explaining, and without reserve, that he would make an exhibition of the instrument in a few months more. As Mr. Edison is himself so deaf that he hears no more quite sure and with considerable vigilance, his confidence was reposed in his purpose; and his marvellous success in developing the 236 inventions which now stand in his name on the books of the Patent Office presented a wide belief that he could really do what he had set his hand to. This confidence seems now to be justified and realized.

As Mr. Edison's public friends stepped out of the hour laboratory where his spoolers are born to the hour of his residence, a waiting sixth, their hope half a dozen ear trumpets in their hands. These implements looked extremely much like ordinary ear-trumpets, only they were five or six feet long.

"I stood here the other day," said Edison, turning his ear over to the reporter of the Graphic, "and I can one of these to my ear. I heard several things very distinctly. I heard a dog cry; I heard the instrument tick down at the station, 1,000 feet away; and I heard one curious, startling noise sound that I could not literally tell I followed it up and found it to be a locust, one of self-clearing grass, 6,000 feet distance—by-fifths a mile.

There were present on the porch, Edison, Professor Bedloch, Secretary of the Edison and war tattoo, Ulrich Palmer, a noted Washington journalist; Wm. Orton, president, President of the Phonograph Company; Charles Batchelor and several other gentlemen eager to see the experiments. They had waited for a pleasant day.

They carefully arranged a series of stands to express "Lizzie" and "I do not hear" by waving the trumpet over them.

Mr. Batchelor and Ulrich Palmer took one of the ear-trumpets and went fields, across the field, to a spot 400 feet distant.

One of them then said: "Do you hear me now?"

They stated they in the porch, with a touching accompaniment, for the voice was distinctly audible to all with the naked ear.

"Do you hear this?" be repeated, in a lower tone, scarcely audible.

Assent he was answered in the affirmative.

The speakers was repeated over and over till the ear trumpets had to be used. At last came on the words: "I can hear you distinctly now; do you hear me?" But Palmer was 600 feet distant, yet his whispers were perfectly audible. Batchelor walked away from his fifteen feet and repeated that he could not, with the unaided ear, hear the conversation whispers, which were audible to us in the porch. At 600 is to fifteen, so is Edison's ear trumpet to the unaided ear—twenty to one!

But the experiments were scarcely begun.

Batchelor and Palmer walked off across the fields till they were a mile distant. They crossed many undulations—up hill, down dale, now vanishing, now reappearing, till they finally stood forth on a hillock in the twilight, a mile away from the house.

Words were exchanged. All ready.

One at each end put the trumpets to their ear.

"Pretty brilliant" said Bedloch. "He says 'Mary Brown's keep lies meandering in the grass.'"

Then to smile towards the figures on the distant hill, "I heard that distinctly. How loud are you talking?"

"In an ordinary tone of voice," came in response to the man with the trumpet; "accurate louder than would speak in a parlor."

Then the test was resumed. It seemed very strange and necessary to hold a conversation in an ordinary voice with a man a mile off, without a speaking-trumpet and with no wire or electrical assistance whatever.

"This is really telegraphing without a telegraph," exclaimed Bedloch.

As we could plainly see with our opera-glasses that the man on the hill had his trumpet "in position," Mr. Edison stepped to the front of the porch and spoke to them, clearly, but in a voice that could scarcely have been heard 200 feet away: "He a mile better off and get in range."

We noticed and remarked about the phonograph and telephone, and the new sound examiner of Mr Bogbeaten, Boston, which Edison declared "a splendid scare" from the principle of his carbon telephone, which as Mr. Bedloch said, "I hear distinct."

But we could not see them anywhere. They had vanished.

"He says," Mr. Bedloch repeated, "Now is the winner of our disclosure; four \$11 a secret, and I haven't got a cent."

There was a laugh at this, and Edison announced from the other end of the gang that he had found them. They moved nearer 500, and their white flag was just visible through the distant trees.

Salutations were exchanged over the two miles of intervening ground, and an opportunity was furnished to all present to hear the wonderful phenomena.

The ear-trumpet, or "telescraphon," as it is called, is internally a curious combination of funnels centring in a chamber and ending in a wire. Mr. Edison believes Cleopatra's Jayne is complete for the use of partially deaf people a small, inexpensive and compact instrument, which, when concerted with a thin wire to the ear, will enable any one to hear every whisper on the stage of the largest theatre.

Tim Dunning asked permission to describe and sketch the ear-trumpet for Tim Gazette; but was refused permission at present on account of some delay of the patents. But the country and the world will be informed of our new electric toy in any way exhaustive the issue of this latest invention of this marvellous mind—a device which seemingly makes the deaf hear, and which will certainly open new methods of communication to sceptics for telegraph and telephone.

"You are going away for a summer rest, I hear," said Tim Gazette to the gray-eyed inventor.

"If I can get away from this shop," said he. "The inventions of Wizz Mountain inside have accumulated pleased that request at my disposal," he added, laughing. "They are all very well once a locomotive as my successor. If I can get there I shall talk ten minutes one peak to another, with my telephone-phone."

Daily Evening Traveller.

THE PHONOGRAPH, ETC.

MR. EDISON AT HOME AT MENLO PARK

Description of a Visit.

A CURIOSITY SHOP OF WONDERS.

A \$ visited on Tuesday evening a merry party of the inventions of the young man who has electrified all Mr. Wilton Metlabon, the courteous manager of the Edison Phonograph in Boston, together with Mr. Frank B. Darnell, took the train at the old Colony depot for Menlo Park. The party consisted, also, of Mr. Edison's Mr. Beckus of the Advertiser, Mr. Gilbert of the Globe, Mr. Burns of the Herald, Mr. Weiker of the Journal, Mr. Barnes of the Transcript, Mr. McNally of the Sunday Times, and a representative of the Traveller. The trip as far as Fair Haven was the same as usual. In no way other occasion when a crowd of reporters get together that is, full of wit and good humor.

The Inland did not remain long at the wharf after the arrival of the train. Upon arriving at New York, the Boston party was met by Mr. H. J. Gleason, the general manager, of the Phonograph Company, who accompanied it to Menlo Park. He was in earnest negotiations by the party, and question was plied upon question, while he took with the best of good nature, and conversed with the utmost affability.

Inasmuch as much matter of news was gleaned which cannot fail to interest and instruct, the larger part of it will be given.

THE PHONOGRAPH COMPANY

has a capital of $500,000, and is made up of the following stockholders: Mr. Gardner G. Hubbard and Mr. G. L. Bradley of Cambridge, Mass.; Mr. Charles A. Cheever and Mr. Hilborne L. Roosevelt of New York, Mr. A. H. Pelotet of Washington, D. C., Mr. Johnson and Mr. Edison. The company after organization paid Mr. Edison a royalty of $10,000 as a guarantee of good faith, and agreed to pay him 20 per cent. of the gross receipts from all sources. Almost all the territory in this country has been distributed out to sub-agents, together with parties in South America and Australia. The patent right for Great Britain was sold on a royalty basis to the Microscopic Company of London. The royalty was $12500. France is probably to be controlled by Mr. Parkes and Mr. Roosevelt, a brother of Mr. Hilborne L. Roosevelt, of the company. Mr. Edison has determined to sell no more machines out, but to dispose of them on the royalty basis. Mr. Johnson explained the difference between the

EDISON AND BELL TELEPHONE,

and it is very marked and important. When Mr. Bell came before the public with his invention, Mr Edison was still experimenting with his. While Mr. Bell makes very important use of the magnet, Mr. Edison does not. Mr. Bell's machine may be called the Magneto Induction, and Mr. Edison's the Galvanic Induction. The telephone, like everything else, must have something to supercede as a thing, and the latter in this case was a musical instrument, invented in 1837 by Reis, a prominent scientific German. Mr. Reis published a description of his machine, and Mr. Orton, the late President of the Western Union Telegraph Company, presented Mr. Edison with a manuscript translation of his work. Mr. Edison went to work, developing his other ideas, and conceptive after conception, until he has completed the telephone. A detailed description of the Edison telephone need not be given; but one thing must be said, and that is that in his work he discovered a very wonderful property in the carbon button, which is now used by Mr. Bell in a slightly different form from that used by Mr. Edison's machine. He found that carbon was not a conductor to pressure. So in his machine what may be called the diaphragm is a carbon button. Mr. Edison, in answer to a question, said that electricity is passed through the disc, and against the upper disc of platinum. The latter is connected with the battery. The carbon button is placed between the two discs, and secondary circuit the voice carries and the talker as the sheep carries the lamb and assumes responsibility. Mr. Edison has already experimented in a telephone which will carry the human voice from Menlo Park to Philadelphia, 90 miles. He says that it is as powerful as Mr. Bell's. Both use the principle of the electric current with Mr. Johnson's Improved Jersey City suit.

MENLO PARK.

This is twenty-24 miles from New York, and when the traveller alights from the train he can see at once particularly what he has come for. Before him are many buildings. This time he was in a carriage, a Mr. Edison's engineer, who attended around the party. Mr. Edison's laboratory is a long, low building, with a small wing. This may be seen in a carriage, a very old single. One second story windows being the only ones which are visible from the road. In front of the laboratory is a house on which was erected a handsome observatory. This is used by Mr. Edison's son Edward, who is also interested with his father, and, in that scientific path, suggested the idea of the Phonograph to Boston, together with Mr. Frank B. Darnell, took the train at the old Colony depot for Menlo Park. The party consisted, also, as follows: Mr. Beckus of the Advertiser, Mr. Gilbert of the Globe, Mr. Burns of the Herald, Mr. Weiker of the Journal, Mr. Barnes of the Transcript, Mr. McNally of the Sunday Times, and a representative of the Traveller. The trip as far as Fair Haven was the same as usual. In no way other occasion when a crowd of reporters get together that is, full of wit and good humor.

The Inland did not remain long at the wharf after the arrival of the train. Upon arriving at New York, the Boston party was met by Mr. H. J. MR. EDISON.

"The late Prof. Henry, of the Smithsonian Institute at Washington, always said," remarked Mr. Edison, "Edison was the greatest genius out only of the number, but of any age." Mr. Edison struck each one of the visitors by the hand, and expressed much gratification at the visit. He is a man of medium height, with a full face and fair complexion, and has a pleasant and energetic manner.

The party shortly took a seat at the table where the phonograph sat, and proceeded to display exhibition of its powers. The physical appearance of an issue of the machine. Mr. Edison takes a tight, strongly wrought iron—cheaper later in the day for a bit less than a dollar—and on the face of it he has wound on a dark cardstock cone and wax with the utmost tenth, and was utmost deceit of securing the diaphragm. This is a thin sheet of mica, and great pains are also taken in using its finger. Apparently he is a man not above thirty years of age, and he has a pleasant and energetic manner. He says he has not heard quite perfectly in his left ear, but very good eyes, over which the lids close very often. They are unusually large, and have quite a heavy mass of eyebrow. His face is smooth and shaded eye with a heavy mass of eyebrow.

If you look at him when his face is turned at a profile, you fail to discover one wrinkle. If an expression of thought or study ever passes over his face, it just above the temples it is nothing private into his countenance lights up and the sweetest and most pleasant smile imaginable takes its place. His mouth when a wrinkle is in it. His mouth is not an unusually large sequence. It is small, firm and artistic, and the reflection of a nervous possessor of the head is of no common stock, and the hair is brushed back from the forehead in a way that the forehead is generously developed. It is not the size that the back part of the head from the crown to the nape of the neck.

Reporters said, "You may think it strange; but if I wanted a thing done I would select a man with a head like that." Mr. Edison is a man of the highest order of the intellectual type, and a man of tact and work, with little discretion as to its result.

Conversation has been written below.

HIS RELIGIOUS VIEWS,

and far from correct. Mr. Edison believes in a God, but does not believe in the Bible as a revelation from the Creator. He is not a regular attendant of church. He thinks that religion is simply the demonstration or school of philosophy, but approaches nearer to the truth than any other. He is not a believer in a personal God, but thinks that it would be no more difficult for God to be omnipresent than to be omnipresent. He is unable to say that he believes in the existence of a God, but he is not an atheist. He is a believer in a God, but he is not an atheist. He is a believer in a God, but he is not an atheist. He is a believer in

great as before and irresistible as ever. Now the poor old man is dead and buried, and his fame lies in a very interesting and important fact in chronological superficiality.

Mr. Edison tells us as follows: It is well known that distance lends an enchanting, barbaric parure of Finance, gets madeo for some of his best heads as fit-ting as a Bond Street tailor's. Distance lends to the telephone its well-known power to make everybody in the sunlight. There is of course a shadow. This shadow practically forms, in outline a human face, and of round ground and filled in makes an excellent profile. Distance lends to the telephone its well-known enchantment. Supposing a man, say the Jew in Mrs. Hemans's Fall of D'Jasus, be subjected into its crucible, and he comes out a Jew, and a very cultured Israelite withal. Distance is worse than useful as for

"Alone through gloomy forest shades
A soldier will by night, etc.,"

but a confusion of sounds, giving, indeed, the letters as follows:

A
Gigh three rattles a
Ghastly groans and ghostly sounds.

Mr. Bernhardt tried this experiment yesterday with "Mary had a little lamb," and it was successful. He also performed several times in succession the words "one, two, three, and four," and the little machine replied, "one, two, three, and four." Mr. Bernhardt also recited the distinguished persons prosaic: "Give 2—3, thou dog, etc."

Mr. Edison says that of all the languages the best for the phonograph is the Latin, and in illustration of it he gave a few lines of Virgil's Æneid. He also spoke a few words in Greek, but the machine was not strong enough to do it very well. He said and it did it after "Operibus sic flexibili" "Ut, nostrorum, nos, nos" and "Mary" was effected unsatisfactorily.

REVITALIZING THE RECORD.

In order to show the permanency of the telestereotoun in the fut ure the Hitherby with which they are to be connected, Mr. Edison has invented a device by which the records can be made to note the rhythm, and most unspeculiarly way. Even if the breath be taken against the diaphragm the intonation seems to indeed same, but still the reproduction can be made to sound like the original voice. Mr. Edison says of it: "For instead of strengthening the record, or in other words, of paving indentations from the fat to the lean, we simply paint the lean with a coat of grease. There is a nothing here was the fulcrum what to rest on, giving thereby a short and long arm. On the long arm is a fine camel's hair pencil, which rests on the small and large surface, the small effects opposite the short arm of the lever.

The hand is covered with fur, and the pencil is moved by touching the fur. Just as the record passes under the pencil the latter has the contact with the record, and as each indentation are irregularities in the surface, which cause the pencil to rise and fall in accordance. One foot touching the pencil moves it about one-thirty-second of an inch. The record thus receives the impression. There are twenty-five words in "Mary had a little lamb," and the little machine will reproduce them clearly to the listen. One in 10, rendered, and, finally, in ten times half of each revolution.

Mr. Edison says that he believes if there are sixteen threads to the inch, and twenty notes and forty-five words, there are about five thousand words enough to take up three octaves of the New York Herald. If there are ten thousand words to the inch, and if the machine is run at high speed, the whole world in 60,000 words. If a song was sung distinctly quick with the tongue it pronounced 200 words in the minute, and if it was sung slowly it would take 1,000 words. There are the words, "Now is the time for all" through brought out by the vivid.

Mr. Edison continues: little contrivance and a sensitive tongue and a piece of paper are certainly on a stand. One other thing is the fact that the machine is very accurate. On the opposite side is another fine, a coat of cork, then a piece of rubber, and then a piece of metal. The cork and the rubber are in a cage, the little needle, which passes on rather rails rigidly on a smooth wheel instead to one of the ordinary screw.

On the other side of the rail is a larger fur-coat, probably as soft in character. If the voice be one, the needle will not appear that it vibrates very rapidly and causes the diaphragm and forward with great rapidity. The needle is then drawn back over the fur-coat by the small wheel by hand, and as fast does it go its to-and-fro vibrations that you cannot see it. The record is then run back to the starting point through the wheel and the quality of the tones of the voice, whether harsh or soft.

HARMONIC MOTION.

The harmonic engine is one of the most wonderful of Mr. Edison's inventions. It is a machine which will sort thousands of messages and go to the right wire every household. The machine consists of a tuning-fork, which vibrates at the rate of 100 per second, or the tuning fork is set to make 100 vibrations per seconds. On the outside and a small wire, which is connected with an electric battery.

Three magnets are connected and theoretically Mr. Edison says one side of the power of the magnet within others per unit 3-10. Another fits, there is another magnet, and so on. The first magnet in the circuit was made by some of the parts to pull back at the time of the tuning fork by other successive forces. The armature of the magnet is attached to a spring, and the spring is attached to a pencil.

The utility of the machine lies in the fact that it is impossible to get in unless each the machine which is in Mr. Edison's possession consists of fifty-two sets of wires in all hung on a frame. Each set is tuned to a different pitch, and the pitch of each one is different from every other set. The machine will be watched by

THERMOPILE.

While Mr. Edison was experimenting with the telephone he found that the carbon button possessed some peculiar properties, and was very susceptible to the influences of heat.

In the early days of the telephone, made primarily of rubber, he found that the heat of his hand would materially affect the results of the galvanometer. He then enlarged the handle to touch, but still there was an effect that was inexpertive and last he made the handle entirely of wood. This, however, did not do away with the electricity long and taken to the inventors by Mr. Batchelor. Mr. Edison, who was upstairs, was then informed that the heat of the hand could not reach and he said he would not believe it was so doing.

Batchelor was then at the handle and the materials gave off several results which were transmitted over the wire to Mr. Edison. The old Thermopile was produced the desired result and the electricity was then tested on the telephone.

TELEPHONOSCOPE.

This little instrument is on the bar what the telescope is to the eye. As the eye receives and transmits the rays of light to the brain, so other words, the eye, or the ear, receives and transmits the voice. One of the eye is matter by means of the telephone Edison invents as many as it invites a day from all parts of the country, from persons who are deaf. A deaf person can hear by the telephone. Mr. Edison has not "designed to do this" it is the consequence. Mr. Edison proposes to invent something which can be seen by the telephone. It is called

In the table of telephonoscope a device has been put in every of thousand street letter-box within a hundred miles from any one in the world have a telephonoscope in their house. A compact paper tube, set, and by it connected with the telephone, nearly a quarter of a mile off, and hand of hand who wore as many as two miles off. Mr. Edison says that the telephonoscope is the most perfect instrument for facilitating the correspondence between distances which demand prior attention.

MUSICAL REPETITION.

This machine needs but a brief description, be-cause it is simple. Mr. Edison says: "Sing into it words, five times." Then in a second, about 50 whole tens are a number of slightly-varying wires which will be found to be so small as to and so the sing into it once.

This needle plays upon a strip of paper, through which no static electricity is readily possible. This paper is rough and resists the needle to fall into the indentations made by the vibrations of the voice. In the wire drawn on the paper with a speed of 10 inches. The paper is electrically scrapped, being passed between two metallic surfaces.

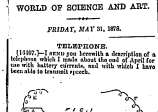
Mr. Edison says that all the languages are best for the phonograph is the Latin, and in illustration of it he gave a few lines of Virgil's Æneid. He also spoke a few words in Greek, but the machine was not strong enough to do it very well. He said and it did it after "Operibus sic flexibili" "Ut, nostrorum, nos, nos" and "Mary" was effected unsatisfactorily.

The English Mechanic
AND
WORLD OF SCIENCE AND ART.

FRIDAY, MAY 31, 1878.

TELEPHONE.

[11402.]—I send you herewith a description of a telephone which I made about the end of April for use with battery current, and with which I have been able to transmit speech.



Since making it I have read with much interest the account of Professor Hughes's investigations. Fig. 1 shows the transmitting instrument, which is made as follows:—a, ordinary telephone cover; b, diaphragm; c, hemispherical piece of boxwood, 1 inch in diameter, and 1 inch thick, hollowed out as to allow it to fit tightly; d, screw, which holding from instrument. To adjust the instrument, screw d (which must fit the case rather tightly) so that it touches c. To ascertain whether it does or not, place an electric bell in the circuit, and if it rings feebly it is all right. All that is then necessary is to fix the cover on the case. Fig. 2, using ordinary Bell telephones and battery.

I would, in conclusion, say that the arrangement above described is only for rural for experimental, and it might be improved upon; but as a proof of the possibility of transmitting speech by the aid of battery currents it is all that is needed.

Nota Bene.

WALKER'S IMPROVED TELEPHONE.

[11403.]—Noticing your editorial note on p. 359 regarding my improvements on Professor Hall's telephone, I think it is right to M. Tressel, as well as to myself, to state that the form of the one I am now using is entirely different from his; it being a pot in ignorance of any details of his method of increasing the sound. I cannot, of course, be sure as to this; but I can be, and am, clear on one point, and that is, that the plan I have adopted, whatever may be its merits, was not suggested to me by any of Mr. Tressel's writings. Further, I may state that I was not in possession of his method, even individually, until after steps had been taken to test my own method. It is difficult to describe the latter without the aid of drawings, but the ideas upon

THE MICROPHONE—CROSS HAIRS.

[11404.]—I may make some twelve dozen of the microphone and can assure you that the following simplified leave nothing to be desired. It is as follows:—A piece of pine about 6in. × 2in. is roughly planed and forms the base of the instrument. Upon this a pad of blotting-paper, same size, and soaked in a weak solution of sulphuric acid, is laid—this above this a plate of carbon, same size. The carbon is prepared by cutting it with a fine saw, carefully, a score, at each end, but touching the size. At one end a piece of wood, 2in. × 2in. × 1in. is screwed or glued, and on the top of this a piece of carbon, 2in. × 1½in. × ¼in. is securely fastened. A thin strip of carbon, like an ordinary French nail, is placed in a depression in bottom carbon plate, and split loosely into a small adhesive, to top plate, a small piece being filed out to a nine cups cubical of carbon. A nail, piece of copper, brass, iron, steel, or platinum wire, or almost any wire may be used, the softest being the best. With such an apparatus as this conversation can be carried on quite well by simply resting over the carbon plate or the nail, or with a round hole break is overwhelming. The point in my modification of the microphone is that of microphone and battery being in one small apparatus, and not two, thanks to "C. E. S." for calling my attention to some of their respecting cross hairs. For this purpose I am sure that fine human hairs would be much the better to use.

W. J. Lancaster.

[11405.]—The Microphone.—Mrs. make a microphone as described by Professor Hughes acts perfectly, the touch of a single hair on a needle point being sufficient to make a needle a much louder transmitter than the ordinary. The battery power necessary for a single instrument is very small, and a single cell charged with zinc water will do well, and, of course, this cell remain in action a long time without attention. The instrument, however, as it stands should be used with the microphone, but for short distances it is neither necessary nor desirable. I use for my telephone a small mahogany box, and placed behind a diaphragm of iron, plane, receiver and another small; most likely because the soft iron is not so liable to be affected by the action of the other magnet. With one cell it is necessary, but necessity for using Bell's patent telephone.—E. P. G.

THE DAILY TELEGRAPH, WEDNESDAY, MAY 22, 1878.

SCIENCE has lately given the world three new separate inventions as marvellous, delicate, and prospectively useful to mankind that it is hard to say which can be called the greatest prize of discovery. Indeed, they belong more or less to each other, and are mutually supplemental, like the famous fairy-gifts in the story of PRINCE RASSIE. That Arab tale relates how three Princes who laid claim to the hand of one and the same Princess were sent abroad by the Sultan her father to settle their rivalry by seeing who could bring back the most wonderful article. Each was favoured by a special protection; and thus one obtained a magic pomegranate which would cure all diseases; another an ivory tube which would enable the most distant objects and scenes to be brought close to sight; and the third an enchanted carpet, by sitting on which you might be transported anywhere at will. The Princes met at a rendezvous far away from their home, and exhibited their treasures with mutual consolation, each declaring his failure of the fair reward, when it occurred to them to test the ivory tube at once, and see by it what the lovely Princess was doing. To the grief of all three suitors, she was plainly observed lying upon a bed of sickness, with the Court in tears and despair around. Thereupon the magic carpet was brought into immediate requisition, and, the lovers having flown through the air upon it, the instant and happy cure of her Royal Highness was effected by means of the enchanted pomegranate. If any one forgets how the knotty question of pre-eminence was finally settled between those three fairy gifts, each of which had proved so useful, we must leave him to turn back to this *Alf Leilah on Leilah*. Just so difficult, however, it would be now to decide whether the palm of merit should be awarded to the Telephone, the Phonograph, or the Microphone, the three latest and most extraordinary gifts of science to our time. All three inventions are closely affiliated in the order and method of their discovery. The telephone, which "wafts a sigh from Indus to the Pole," is by this time sufficiently understood, though by no means yet valued as it will be when the ingenious minds to which we owe it have had time to perfect their apparatus. The phonograph, which actually records speech and sound in a portable and reproducible form—outdoing the chimes of marvels of the Arabian story—was discovered by Mr. EDISON, it is said, while sitting with his pen-point pricked his finger, and, as he drew it away, made an interrupted line of blood upon its surface by the vibration of the point, whereupon he at once placed some MOSAIC paper so that the diaphragm would travel over it, and, speaking through the tube, found small but faultless "dots and dashes" inscribed. Reversing the process, and so managing the impressed paper as to make the diaphragm vibrate, it repeated to him falsetto the "Hallos" which he had shouted at the machine. We might fairly say that was the voice of Science herself rewarding a great inventor with one of the most magical of her hidden secrets, for Mr. EDISON went to work forthwith, and, neither eating, drinking, nor sleeping for two days and nights, toiled until he had produced and brought into working order the first phonograph.

The microphone—the last of these amazing discoveries in that subtle region where electricity, magnetism, motion, and sound execute their invisible interchanges—has sprung forth to startle and benefit the world in much the same capricious way. A paper lately read before the Royal Society announces the invention by Professor HUGHES of this astonishing instrument or apparatus which opens to our ears a universe of sounds hitherto inaudible—just as the microscope revealed a world of minute life and structure unknown before. Like Mr. EDISON, Professor HUGHES was one day employing the telephone for various acoustic experiments. He wished to investigate the effect of numerous vibrations upon the electrical behaviour of conductors, led to this idea by the way in which selenium is known to become electrically affected by light, and also by the researches of Sir WILLIAM THOMSON upon the electrical conduct of strained wires. The Professor had a stretched wire on his telephonic circuit, and, though he talked and plucked at it, no effect followed until it broke. At that moment the telephone uttered a sort of "shh," which was very curious. He placed the broken ends together under a weight, and obtained again faint sounds, which were improved when the wires were connected by iron nails, or a steel watch-chain—the more pieces and more diverse in substance from the conductor seemingly the better. Experimenting still further with his broken circuit, especially in the direction of this whisper from Science about "More pieces," he found metallic powder or fine metal filings wonderfully augment the power of transmitting sounds; while shot in a bright carbon, platinum, carbon, and mercury also gave good results, particularly the last. Following up this clue, Professor HUGHES hit upon a plan of suspending finely divided mercury in a stick of charcoal by hooking the latter and plunging it into quicksilver, whereupon the charcoal became infiltrated with the mercury in minutest but continuous particles. Inserting a "trace mitter" of this sort in his circuit, an absolutely amazing sensitiveness to sound, as well as power of conveying it with the utmost fidelity, was displayed by the apparatus. A touch of the finger on the vibrating plate was conducted to the speaking end in volume of vibration like the rustle of a forest; the stroking of a camel's-hair brush on a card was magnified into the sound of a loud whisper; the beating of a drum, of the most distinctly caught like that of some slegged horse trotting, and it was, moreover, heard to trumpet from its raised proboscis like an elephant in an Indian jungle. Sounds, in fact, totally inaudible before to human ears were arrested and reported by this simple and accidental expedient of interrupting the electrical circuit with a finely-divided conducting material. There is almost no doubt that the perfected Microphone will convey to us that hidden world of life now rising in growing trees and plants which HUMBOLDT and others might be a continuous melody in the auditory organs of earth's smallest creatures. The "music of the spheres"—who could only find a way of localising the vibrations of a star, as we can listen and examine its light with the spectroscope—would possibly become audible to us; and LORENZO, had he known of this magical invention, need not have told JESSICA that we should never catch a note of that cosmic anthem which each golden orb in his motion like an angel sings, still quiring to the young-eyed cherubim." To "hear the grass grow" has become, by this exquisitely delicate discovery, no longer an utterly inconceivable exercise for sharp ears. It may be expected to replace the clumsy methods of the stethoscope and sphygmograph with a most accurate appli-

cation, which will tell the doctor how exactly most the heart and the pulse have to say about his patient's case. Some application of it, by presently employing a little portable battery and circuit, may probably be hit upon, which will greatly alleviate, or even wholly remove, the disabilities of the deaf. But, more than this, while magnifying audible sound, and reporting to us tones which were before inaudible, this new invention is said to solve all difficulties as to articulateness in telephonic transmission. It conveys speech, or music, or the slightest inflections of accent and timbre, with perfect distinctness, and with a power or amplitude that it increases indefinitely that which the telephone has exhibited with a homogeneous conducting wire. In introducing his admirable discovery very modestly to the Royal Society, the inventor remarked, "It is impossible to say what may be the applications or effects of that which I have had the honour of bringing before you;" and to his great honour Professor HUGHES added, "I do not intend to take out a patent, as the facts I have mentioned belong more to the domain of discovery than of invention. No doubt inventors will ere long improve on the form and materials I have employed. I have already my reward in the distinction of submitting my researches to the Royal Society." This is, indeed, a spirit worthy of such great services to human knowledge, and Professor HUGHES has exhumed the fame of his invention by the splendid manner in which he gives the world the full benefit of the discovery.

Although difficult to convey, the explanation of this wonderful power of the "microphone" to magnify sounds does not seem beyond the reach of simple phraseology. "There are two wave-currents running through the telephonic circuit —one of electricity, the other of sound vibrations—and the effect produced by the latter in modifying the resistance and conductivity of a circuit is little or none, so long as the wire remains homogeneous and continuous. If, however, a portion of this be, as in the transmitter, composed of a series of very minute subdivisions, electrical continuity being still preserved, the successive waves are no longer neutralised in their effect upon the electric flow. The molecules of the mercury are thrust together or drawn apart, becoming alternately longer and more resistant, or shorter and more compressible, so that every briefest and smallest sound-distortion and recoil of the air is made to affect perfance note and record itself in the effect produced upon the electrical flow, and the variations of these electric currents reproduce the order, force, and modulation of the sound. With diagrams this theory of the action—which is the one put forward by the accomplished inventor—might have been rendered much more intelligible; but it is said to afford considerable notion of the manner in which the microphone is thought to work. As its name implies, it is the magnifier of sound, and cannot fail to reveals as well as carries sound, and cannot fail to prove an immensely valuable addition to the telephone, while it may be confidently expected that the phonograph will be made available for recording by its help some of the unexpected things to which we shall be enabled to listen through this fairy gift of science. It has been suggested, for example, that molecular motion itself, under certain circumstances, may be conveyed to our ears by this apparatus. We may overhear, for instance, the inner vibrations of a mass of heated metal, or the sound produced by chemical combinations and reactions. Stop by stop man thus explores the

tuitous marvels and resources of that world of Nature which is at once his palace and his prison. Each great secret wrested from the silent but beneficent Spirit of the Universe confers new powers and makes life richer and more commanding. Is it, then, the caprice of that spirit which has imparted these two splendid secrets of the phonograph and the microphone by apparently the most trivial accidents? A pricked finger produces one for us; a broken wire led Professor HUGHES to discover the other. There is no caprice in this mystery. The hour comes, the patient seeker is on the right road, and, at the moment when he least expects it, Nature discloses her hand, and shows another of those far-reaching treasures of knowledge which she keeps for him and his like, the best benefactors of mankind.

ST. JOSEPH DAILY HERALD, THURSDAY, MAY 23, 1878.

THE PHONOGRAPH.

SHAKING HANDS WITH INVENTOR EDISON.

A Walk Through His Laboratory.

How the Great Electrician Looksand Acts.

Correspondence of the St. Joseph Herald.

NEW YORK, May 17.

In the 6:35 P.M. train on the Pennsylvania Railroad yesterday, was a special car, filled with a select and jolly party of excursionists, who by invitation of J. M. Tower, Esq., of this city, were to pay a visit to the remarkable man, Thomas A. Edison, and examine some of his wonderful inventions.

Among the party of forty, one third of whom were ladies, was noticed James Craig, Col. Osborne, and Winslow Judson, with whom you readers are acquainted. The forenoon, written by one of Edison's electric pens, wound up with the remark, "The fun of the moon," and as we were not to return to New York until 11 at night, every one had lively anticipations of the novel visit and wonderful sights, the country scene and pure, fresh air of the fields, that we were to enjoy at the "hall of the moon."

Menlo Park (Edison's home) is over in Jersey, twenty-four miles from New York. Leaving Jersey City, we crossed the swampy meadows at its borders, sped through Newark and Elizabeth, and within an hour were landed at the little flag station of Menlo Park just as the sun was sinking low.

From the station we ascended directly several flights of stairs, until we stood upon the veranda of a bluff—a crowning table land, level and green, overlooking the surrounding country, and reclining in the choicest air of heaven. The place is a perfect paradise for a poet or an inventor. The night scenery alone is marvelous, and they comprises the town, built on the sides of an immense square, with abundance of room all around each, and unobstructed by fences, flag stone walks, and imposing appearance. There is no hotel, no saloon; the nearest approach to business is found in the necessary "grocery" on the corner. But Menlo Park, though a western town, has great expectations, and the owners of the soil regard it as a suburb of New York; prices are held up, and the whole range of a young city is sketched in their hearts. The future is pregnant with numerous great events, and perhaps includes such a transformation. Judge when a quiet place this is! Why, a man can almost hear himself think, the stillness is so profound.

The chirping crickets ratified their music, as in the mellow twilight, we, two score curious people, wended our way to the hill, and across the meadowlands, to the usual path of travel. Shortly we came in sight of, and facing us, the "hall." It is a two-story frame building 50x100 feet, the front ornamented with a veranda. It looks too large for a house, but too small for a factory.

Time has dulled the white paint, soiled the color, worn the steps, and some panes in the shutters are windows are broken.

Curious eyes look carefully at the building, for we are told it is Edison's workshop, and that information gives a peculiar character to it, common enough or not by itself. It is no longer a plain wooden-framed and clapboarded house, but as the working house of a genius, it partakes of his fame, and in our eyes, is for us, not so measured by his achievements, that we approach it almost with reverence. We see continuous lots of steam escaping from its side, and they give pleasantly to our excited feelings, regarding the life and work within.

One lady exclaimed, "I approach that building with awe."

Visitors find within its walls the most remarkable collection of machinery, articles, and things imaginable. The back half of the lower floor is used as a machine shop. Here the boiler glows; the engine whirls; the shafting spins, and men with blackened and greasy hands and faces, are attending the lathes, drills, and other machines, which are so thickly placed that a novice or visitor, cannot with safety walk among them. It was evening, but the gas was lit and men were fully at work. An hour hours here, but night and day are both employed, Mr. Edison says, working far into the night.

We noticed that the workmen who allowed a friend their job, were foreigners, and we took them to be Germans. The intelligent countenance of the machinist differed from those a foreigner. In the front half of the floor are a number of large glass cases filled to repletion, with scientific apparatus, models and curiosities, and upon benches, manuscript articles, and a thousand other things, that we don't know any thing about, are scattered around. The party began to trench in here, but it was stated that Mr. Edison would receive them upon visits, so we proceeded to the second floor; on the way up, peeping through the windows of the chief's private study, we saw the dirty dishes of an unfinished dinner. Upon mounting the stairs and steps, we entered

EDISON'S NEW BABY.

HOPE FOR THE DEAF—THE GENIUS OF MENLO PARK INVENTS A NEW EAR.

The inventive powers of Professor Edison appear to be illimitable. The world is startled by one marvelous invention, and before it has time to take breath another contrivance, either an immense improvement on some former one or something entirely novel, is thrown out.

The latest production of this genius is what is known as the "carbophone," on statement to the correspondent of the Associated Press, between the telephone and phonograph, a very desired patent entirely independent of any previous devices or any existing forms. It consists in charging the focus of the trumpet attached to the phonograph to reproduce the sound registered by the voice.

In the first phonograph the trumpet was a tin or paper funnel; the new attachment is made of carnelians globules and the carbon button which so largely enters into the composition of Edison's telephone and which is sensitive to the point of transmitting the sound of the breath. The new trumpet is modelled after the convolutions of the human ear. The fabricated sound wave is made to recall itself through the medium of the diaphragm upon the receptive piece of tin fail as deeply as the musical tone uttered under ordinary conditions.

This trumpet, as the inventor has had practical experience (being somewhat deaf), is destined to be the greatest boon to persons afflicted with hardness of hearing. Attested to the ear (instead of the phonograph), it will so conduct sound vibrations as to enable a person to hear what is said one mile, slightest sound, even that of the ticking of a pin. In a crowded assembly it will enable a person with the words of a speaker at an almost incredible distance. With this remarkable invention in hand, the world would not be much surprised if there should soon rise from some inventive genius Park or instrument that will enable the deaf to hear and the dumb to speak.

THE NATIONALS.

HARRISBURG, Pa., May 21.—The Executive Committee of the National party met to-day. The declination of ll ujudge R. Bentley, trustees for Supreme Judge, and Christopher Shearer, for Lieutenant Governor, were received. Judge Agnew was then unanimously nominated for Supreme Judge, and Daniel M. Rook for Lieutenant Governor. Judge Agnew is undecided whether he shall accept the nomination for Supreme Judge, tendered him by the National Greenback Labor Committee to-day. The Committee appear to be satisfied that he will stand the nomination, but the Judge informed your correspondent that he should determine his decision, Judge Bentley's letter of declination being received to-day partly with the principles of the National Sentinel

EDISON'S PHONOGRAPH.

A LOUD-MOUTHED DELEGATE COMES TO THE BAY FESTIVAL.

He Talks Through the Wood Steam-Exhibits the Phonograph—Says that the Chinese Must Go—Etc.

The exhibition of Sumner W. Burbie, telegraphed in New York a little more than a week ago last Saturday, for an Edison Phonograph, to lend a new and wonderful variety to all the other delights of the monsieous Mer Festival, was wandered for the arrival here on Sunday night of. P. Osbor, in charge of a specimen of the marvel of all the centuries. It was tested by him yesterday afternoon in the presence of a few Studios and a number of reporters, and the performance was a success. The construction of this little instrument of sensitive possibilities is so simple and has so frequently been described that a repetition is hardly necessary. At either end of a plain cast-iron base, about sixteen inches long and six wide, a cast-iron standard six inches high. Through a screwed hole in each of these standards runs a screw an inch in diameter and of a very fine thread. In the center of thisscrew vA cast-iron cylinder four inches in diameter and six long. The surface of its exterior is covered to a fine spiral thread, screwed with that of the screw. Around this surface is rolled a length of

ORDINARY TIN-FOIL.

Four brass rods connect the cylinder's mouthpiece about two inches in diameter with one extreme part of its wonder of the age, and the latter part is also mounted on a brass rod. Osbor explained the principle on which he controlled the artificial diaphragm. This latter is merely a thin disk of mica or heavy mica paper, ten inches in diameter, and in the center of this disk is a small hole, in which is inserted a steel point, resembling the head and half of a fine cambric needle. This is set perpendicularly to the disk, and the point of the latter is adjusted so that the needle's point just touches the tin-foil on the cylinder. The second latter is then put in motion, and the needle point, being attached to the membrane, must trace forever for the amusement or instruction of generations. Mr. Osbor turned the crank and all the screws and rods began to revolve. Then he placed the needle point delicately on the cylinder and said, "Good morning, Mr. Phonograph." He then turned back the cylinder and repeated the salutation. Both times the needle point responded the words, and again commenced to turn the cylinder backward. Then he placed several needle points on the cylinder and requested the machine to speak for the result. "Good morning, Mr. Phonograph" rolled out. Mr. Phonograph itself in a voice even more metallic than that of the inventor. The articulation was never once marred through three days away with a feeling of inexplicable awe. The machine was then turned over to the ladies present for criticism. The first outburst proved it to be too

PROVINCIAL ALTOGETHER.

That it has always universally been alleged that the Chinese must go, and that they are necessary to nobody, was the main point about the tests. The very necessity of the conversation, and of the theory upon which the phonograph reasons, the exact opposite of the Chinese theory, made the machine refuse to speak for the result. Mr. Osbor, however, at last succeeded in getting the machine to say what, as if in mockery appreciated the right of free speech. After the machine had been induced by coaxing to receive sentiment it declared to receive

"Oi, am the monsoonay cussut phonograph, I am! What an think of me?" Despite the not unmistakable burst of heathenism which followed, the machine was in the principle of one, one was a success, being, a Lotus, indeed, that it was found to have been the first Chinese phonograph ever manufactured.

WARMED TOO AGE.

Of a sore into the machinery, Mr. Phonograph filled it back again, but the machine was not to be silenced so easily. The prodigy of the age, however, objected. Mrs. Steiner, not at all disconcerted by the hoax into the monsoonsitive machinery, the phonograph returned in the chorus with

If Uncle owns a body dould dey'd be rich.
If a hair have only seen a hole ery.

This was an immense success. It is true the melody was not enchanting, but for the first attempt at a Chinese song by the American Edison of things, the second the Society wants one to sit on that a Hartford Mr. Osbor, who has been giving the wonderful piece of delight since Thursday, returned to the Studios and a number of reporters and visitors to the exhibition of this little instrument of sensitive possibilities is so simple and has so frequently been described that a repetition is hardly necessary. BOSTON HERALD.
SATURDAY MORNING, JUNE 1.
HERALD SUPPLEMENT.

AN INVENTOR AT HOME.

A Visit to the Residence of Thomas A. Edison—The Phonograph and Other Inventions at Their Starting Point—The Personal Appearance of the Inventor.

The name of Edison has become very familiar to the scientists of the New and Old worlds during the last few years, and there have been associated with this name many rapid inflations, that have made him a very many fortunes for those who have followed in the footsteps of the master, and as the inventor of the "talking machine" he is known to thousands better than any man of his years in this country. Since his phonograph has been on exhibition in this city the constant inquiry of visitors is: Has Edison died and been "Where is Mr. Edison?" for, after having seen the mysterious result of this rare ingenuity, the first desire is to know something of his personality, his surroundings and the other products of his brain. The message of the exhibition, Mr. William McKinney, has thus far failed in his attempts to get the necessary information, and the public will, for the public might have been spared time, as Mr. McKinney's invitation, a party of Boston newspaper men, Mr. Edison was at his home in Menlo Park, and under the escort of the skillful manager of the Mr. Edison, was subsequently enjoyable one, and will be a source of many pleasant memories, to those of the party who had never before seen the home of this gifted man and the scene of many of his inventions.

THE STUDIOUS AT HOME.

Mr. Edison has taken for his residence one of those plain if unpretentious houses of which Menlo Park is composed. It is situated on the main street of the village, facing the Metropolitan railroad line to Newark, and is a two-story house on an elevation of about twenty feet above the road. It is a light yellow wood colored building, with a flat roof, and has a veranda in front. Just behind the house is a large building, formerly a dance hall, but now used as a machine shop. The entrance to the house is through a side door, which opens into a hall, from which a flight of stairs leads to the second floor. On the right of the hall is the parlor, and on the left the dining room. Both are furnished in a plain but comfortable manner, and the latter is used as a reception room for visitors. The parlor is the inventor's workshop, and here he spends the greater part of his time. Here are his models, his books, his papers, his drawings, his tools, his chemicals, his batteries, his electrical apparatus, his phonograph, his telephone, his electric pen, his electric light, his quadruplex telegraph, his electric railway, his electric motor, his electric meter, his electric engine, his electric railroad, his electric pencil, his electric—but why go on? Here are the models and the drawings of all the inventions that have made Edison famous, and here he has been working for the last two years on the perfection of the phonograph, the telephone, the electric light, the electric railway and the electric motor. Here he has been working, and here he will work, for this is the home of the inventor, and the workshop of the wizard.

THE BUILDING AT WORK.

The building is an ordinary frame structure about 30 feet long by 40 wide and two stories high. The lower story accommodates the machinery, and the upper story is the home of the inventor and his family. When the writer of this article was here Mrs. Edison was busily engaged in preparing the dinner for the party, which consisted of Mr. Edison, Mr. Upton, Mr. Batchelor, Mr. Kruesi, Mr. Osbor, Mr. McKinney and the writer. The dinner was a most delightful one, and was served in the dining room on the first floor. The table was set with all the delicacies and luxuries of the season, and the viands were prepared in the most tempting manner. Mrs. Edison presided at the head of the table, and Mr. Edison sat at the foot. Mrs. Edison is a most charming lady, and her manner at the table was so free from affectation that the guests felt perfectly at home. Mr. Edison, too, was in the best of spirits, and his conversation was full of interesting reminiscences of his early life, and of his experiments in the various departments of electrical science. Mr. Edison is a man of medium height, and weighs about 160 pounds. He has a large head, and a high, broad forehead, which is covered with a luxuriant growth of dark brown hair. His eyes are dark brown, and are full of expression. His face is smooth shaven, and his features are regular and well proportioned. His hands are small and delicate, and his fingers are long and tapering. He is a man of very few words, and is extremely modest in his manner. He is a man of very few words, and is extremely modest in his manner. He is a man of very few words, and is extremely modest in his manner.

tioned by the inventor to institute the fullest possibilities. The table upon which the instruments are placed is of solid oak, covered, however, with a composition of shellac and powdered clay of considerable thickness, being completed, and the actual size of the table is about four feet. At the side of the table is a battery of 40 cells, which is connected with a peculiar mechanism, a view of the model sent to the Patent Office, looking more like a piece of machinery than any thing else, and around the centre is a series of thin carbon points about two inches of an inch, and alike in outside appearance, but differing essentially one from the other in the degree of angular resistance each is supposed to offer to the electric current passing through them, variety of contacts, the striking objects being the apparent yet inexpensive character of the whole affair, the few cells required, and just enough of the theory of electricity to make it understood by Mr. Hughes—the embodiment of that term by Mr. Edison—the embodiment of the magnificent result—the origin of which, one cannot, a cast of the mind, help associating with the phenomena, the inventor has only to state that it began, 18 months ago, and has since been kept at length, 24 hours each day, at work upon it, and that he must return to further such a statement, filled with anything from a razor and shaving cake, to a piece of telegraphic apparatus. *Edison is a man*, fully developed, possessing every detail to one of the oldest, and most practiced hands, and yet, he is but a youth, and evidently, in the enthusiasm of his calling, entirely unconscious of the fact that he is performing, at this moment, something more of telegraph wizard, than anything and nothing in all sorts of phases, that has ever been done in the whole history of letters, literature or intelligence. Whereas recording is probably known only to the chief operators of the country, as a thing of the past, and the ordinary Morse Register, the common measure of men could have brought together the necessary elements of articles all the same, but Edison, never.

MR. THOMAS A. EDISON

was introduced to the party and stood there could conceal their surprise. Instead of the ordinary appearance of a man of science, or of a man of letters, or of a man of the world, there was no acquaintance existed, or could be formed, who was more entirely unlike any of the three. He is about six feet four inches high bold, and massive every, of a well knit, and powerful frame, and a face more like a Saxon Chief, than any other, and with a nose and mouth that indicated determination, and a head of hair, that would suit a whole tribe, and he had being only five hours later than the party, who had preceded him, and who had remained in all that period, nearly a century, a little more than a half hour's opportunity to look around him, and to see and converse with the wonderful. He had evidently been in the most excessive haste, his coat was thrown on, in both, his sleeves, in both, his pantaloons, engine soiled, and his whole appearance, a picture for and emblem, all of which was in keeping with the hurried notes, proceeding he followed before taking his seat, and which he wrote with a pencil, and on a piece of paper, which he tore from a book, and the fact, that they are all so unexceedingly small, and consequently, so unexceedingly neat, and consequently so unlike the ordinary memorandums, or memoranda, as to cause them this minute, and to be preserved, as curios from this minute, and the pencil, and the paper, and the book, and the hand, and the man, and the whole scene, and circumstance, are all unlike anything ever before witnessed, and as such are destined to be remembered, and recorded upon the sheet of the fact.

THE INTERVIEW,

as soon, with the inventor as quiet, have a name in America, and a reputation in Europe, and a place in the list of men of science, and a regard for the products of his brain, the discoveries, the inventions, the results of his mind, and the fruits of his labors, the benefits of his study, and the blessings of his life, and the improvements of his race, and the experiments formed and executed, and the theories proved and established, and the facts, and the truths, and the evident enjoyment of his success. The inventor was in the best of humor, and spirits, and in the midst of a variety of visitors, that there was no hesitation existed, in the slightest degree, in his communicating every information, and in his showing every thing, upon inviting a section of the chapter, and upon his being requested to open the fly, by the introduction of the [illegible] of almost supernaturalism, and the [illegible] of this [illegible] was suffered, but, in all fair frankness, and with the most unreserved communication, he [illegible] and [illegible] and [illegible] and

NEW-YORK DAILY TRIBUNE, WEDNESDAY, JUNE 6, 1878.

TELEPHONE AND MICROPHONE.

A question of priority of invention seems likely to be started between Mr. Thomas A. Edison and Professor D. E. Hughes, concerning the device which the latter has called the "microphone." As nearly as we have been able to ascertain the facts, they may be summed up as follows: Professor Hughes has displayed and described before the Royal Society, London, an instrument magnifying sounds, by which, for instance, the tramp of a fly may be rendered audible and may be heard through a telephone, miles away. The substance used in this instrument for increasing sound, is carbon through which an electric current is passing. Now Mr. Edison invented more than a year ago his "carbon telephone." There is no doubt that he was the first to discover a remarkable property of carbon—that its capacity for conducting electricity may be very largely varied by small differences of pressure applied to the carbon itself. This singular property is made use of in both the Edison telephone and the Hughes microphone. Such small differences of pressure as sound waves can produce, serve the purpose of altering the flow of an electric current in both inventions. So far, Mr. Edison has every advantage of priority.

In two particulars, however, Professor Hughes presses the carbon differently from the earlier device. His best measures were obtained when the substance was "metallized" by plunging it in mercury after being heated to whiteness; but it does not appear that the carbon underwent any such process in some of his experiments; on this point the accounts given are not perfectly definite. Both inventors tried many different substances, and both decidedly preferred carbon. Among the things which Mr. Edison tried were metals finely divided, and also, bits of fiber coated with metal by chemical means; both these methods have some similarity to that which Professor Hughes employed in the subdivision of the material or metal used. But it was in dividing the carbon into two, three or four pieces that the marvellous effects of the microphone were attained, and this "does not appear to be the same thing as, for instance, Mr. Edison's use of powdered gas-coke or carbon. Professor Hughes evidently thinks that the main power of his instrument is obtained by the use of separate pieces of carbon which are lightly pressed together. His theory is that a sound wave causes the molecules of a piece of carbon to vibrate so that they and it take up more room, and hence press against a larger surface in the next piece. The greater the number of molecules thus brought close together in the separate pieces of carbon, the greater will be the joint capacity of the whole to carry the electric current. Professor Hughes illustrates this by placing three or four pieces of carbon in a tube, barely touching each other in the condition they will not convey electricity. But when waves of sound affect them they alternately approach or recede so far closed that the electric current passes through them readily. Thus it may depend upon the mere pressure of the sound waves whether a strong current, a moderate current, or no current at all, shall pass over the wires in a delivering telephone. In this way Prof. Hughes appears to have secured a wide range of power. In most of his instruments he has been solicitous to shape the pieces of carbon or other material, so that they touch each other with rounded or pointed surfaces; thereby getting the largest contacts with the greater pressures, and the smallest with the lesser sound waves.

The most striking difference between the instruments of Mr. Edison and Professor Hughes is that in the latter the carbon is to be talked to direct, without the intervention of a diaphragm or metallic plate. In a recent article on the subject in the London *Mind*, Mr. George H. Prescott says that all modifications of the speaking telephone "employ a diaphragm as the transmitting and, capable of responding to the acoustic vibrations of the air." In one of the more recent improvements of Mr. Edison's carbon telephone, he has substituted a plate for the diaphragm; but the use is the same, to take up the vibrations of sound, and, while vibrating, to press upon the carbon. *The Engineer* (London) says, "Professor Hughes dispenses with the diaphragm. You speak at the French mills or tubes, and the sonorous waves directly effect the required result." Mr. Edison has invented an excellent telephone, but the microphone as it is figured and described seems like a different thing. It transmits sound from a speaker who may be some yards away, and does not require the voice to be projected through a mouth-piece. Its construction is easily more simple than any of the telephones. Two sticks of willow charcoal stuck into a board, and holding a third stick resting between them, thus ⌅, is the whole of the receiving apparatus in one of the best forms. The problem of using the telephone for reproducing public speakers, or sound, at a distance, should be easily solved by the microphone, which it is said, transmits the ordinary tones of the human voice over a short space, with such an increase of force as to be distinctly loud to the listener.

NEW-BRUNSWICK:
THURSDAY, JUNE 6, 1878.

A VISIT TO EDISON.

On Wednesday, the 5th instant, the officers of the New-Jersey Editorial Association held a business meeting in Railway. Having received an invitation from THOMAS A. EDISON, the inventor of the Phonograph, after the transaction of their business the Editors drove out to Menlo Park in carriages, and availed themselves of the opportunity of inspecting the celebrated inventor and some of his latest inventions. The Laboratory is situated about 1,200 yds. three hundred yards north of the Pennsylvania Railroad station, on high ground, commanding an extensive view of the beautiful surrounding country, and consists of a long two-story wooden building. Telegraph wires extended out from it in every direction, making the circuit of the fields round about, which is two in his experiments. On entering the building one is naturally led to wonder whether it is a chemical or mechanical laboratory. The walls are covered with shelves filled with all manner of chemicals and other substances in bottles and packages; and the floor with tables covered with bottles, magnets, crucibles, retorts, coils of wire, and scores of small instruments which were nameless to us, some apparently complete and others lying around in detached parts, many of which were probably representations of abandoned experiments and others not yet completed. Wheels and pullies were hanging overhead, and the sound of the hammer, the file, the saw and the forge resounded throughout the premises. Some fifteen or twenty men were at work doing things, incomprehensible to us, and which we were informed were making models and mechanically putting into shape the ideas of the inventor. It was a busy scene, and clearly demonstrated that it was a place for earnest and serious work.

On the inventor making his appearance and after introductions, he led the party through his establishment, and directed his assistants to put his Phonograph together, it having been spent when we arrived. He then showed the party his Telephone, and a series of experiments were made by himself and the Editors, in talking, singing, whistling and playing upon musical instruments through five miles of wire. The various sounds were returned in the clearest and most satisfactory manner, showing the immense capability and usefulness of this instrument. Conversations were carried on through the Telephone from Menlo Park to Washington, D. C., a distance of two hundred and thirty-five miles, and it is said to have been done through resisting coils calculated to be over seven hundred miles. This invention alone Edison predicts will soon do away with the ordinary modes of telegraphing, and that the business men in the country will simply sit in their offices and talk direct with men in other cities, instead of writing and sending messages through the operators on the Morse instruments as at present; and we see no good reason why Edison is not a prophet whom every body should believe in this matter.

The Phonograph having been put together, the Editors assembled to his upper room, and there they were introduced to Mr. Edison's chief assistant, CHARLES BATCHELOR, Esq., who assisted in the subsequent exercises. The Phonograph was shown and explained to those present. It needs to be seen to be clearly understood. We found an iron cylinder about three inches in diameter, some eight or ten inches long, on the disk or surface of which were shallow grooves running round it on a spiral, the whole moved on its axis by a crank also on a spiral. On the face of the disk was adjusted a broad strip of tin foil. A mouth-piece was then adjusted over the disk, on the under side of which was a small metallic point which pressed the tin foil over one of the grooves in the disk. The machine was now ready for operations. Mr. Edison first sang a few lines of the old war-song, "John Brown's body lies mouldering in the ground," then reversed the cylinder, when the song was reproduced by the machine in clear and distinct tones, loud enough to be heard all over, the room. Every note and peculiar emphasis or intonation was exactly reproduced, to the astonishment and delight of the visitors, most of whom had never seen anything of the kind before. Experiments were then tried with recitations from "Mary had a Little Lamb," "Bingen on the Rhine," "Hohenlinden," all of which were returned by the machine in the very tones delivered to it. Then experiments were made with musical instruments, singing of various well known tunes, and the sounds and notes were returned in the same key. Duets were sung by Edison and Batchelor, and duets were returned to the listeners by the little revolving machine. Whistling, coughing, laughing, and all manner of sounds that could be thought of by the party, were given to and returned by the machine. Each of the Editors sang, talked, orated and shouted over the little mouthpiece, and the sounds made were hurled back at them with horrible exactness. And what was this more wonderful still, when desired the same piece of tin foil would sweep, sing, whistle, talk and shout all at once and the same time, each sound perfectly distinct from the other and all in the same breath, and made solely by the little metallic point tearing the impressions of the sounds made on the face of the tin foil. The possibilities of the Phonograph were thus demonstrated to be really wonderful, and beyond all conception to the ordinary mind.

The uses of the Phonograph will doubtless be many—the reproduction of public speeches, private conversations, all forms of dictation, music, etc., etc. A merchant in New-York may talk in a Phonograph, enclose the tin foil in an envelope and send it to China, and there the words will be reproduced in the exact tones of the New-Yorker. An 40,000 words can be spoken on a piece of tin foil only ten inches square, the economy of that mode of communication is clearly apparent. As two sheets of tin foil may be written upon at the same time, a duplicate copy may be preserved of the communications. These may be reproduced to-day, to-morrow or ten years hence. Speeches may be delivered, and the reporter take his time in copying the words at any time thereafter,

and at his leisure. The practical uses are therefore multifarious, and only limited by the imagination.

The Phonograph and the Telephone are only a couple out of over a hundred different inventions made by him, and which have made him famous among scientific men. His electric pen and duplex methods of telegraphy are in constant use, and have proved to be of great value. He has also invented a machine for measuring starlight, one to measure the rays of heat from hitherto unknown distances—from the stars, even—which we have no time to mention to-day, notwithstanding he was polite enough to show and explain some of them to his unscientific audience on Wednesday. For nearly two hours Edison kept the Editors busy in witnessing his experiments, and showing them about the premises, all the time filling them with wonder and delight. They finally took their departure, fully convinced that the Phonograph is one of the wonders of this wonderful age, and that the greatest wonder is Edison himself, and that if he had lived a hundred years ago he would have been hung or burnt at the stake on the charge of being a wizard.

Entser, the inventor of the Phonograph, has partially promised to accompany the New-Jersey Editors on their Excursion this year, and take his Phonograph and Telephone along for their instruction and amusement. We expect to receive a positive answer from him in a day or two. His promise among the Pressmen of the State will be hailed with delight from Sussex to Cape May, and he may expect a warm reception. Except needs just the sort of recreation that such an excursion will afford, as we fear he is taxing his strength too much over his inventions.

DÉPART DE SAVANTS FRANÇAIS

Les astronomes français venus en Amérique pour observer le passage de Mercure sur le Soleil le 6 mai, MM. André et Angot, sont repartis mercredi dernier pour la France à bord du steamer *Ville de Paris* de la Compagnie transatlantique. Ils se louent beaucoup de l'accueil qu'ils ont reçu en Amérique, et ils sont surtout enchantés de la petite tournée scientifique qu'ils ont faite depuis leur retour d'Opelon.

A Boston en particulier, d'où ils sont revenus directement à New-York, ils ont pu se croire en pays français. M. Nathan Appleton, dont on trouve le nom mêlé à tout ce qui intéresse la France en Amérique, les attendait à la station du chemin de fer, pour les conduire à la maison de son illustre père, M. Th. Appleton, qui n'a pas voulu, pendant leur séjour à Boston, qu'ils prissent place à une autre table que la sienne. Grâce au concours empressé de ces deux amis de la science, le temps passé à Boston a été merveilleusement utilisé. La première visite de MM. André et Angot a été pour les ateliers où célèbre Alvan Clark, où ils ont été mis au courant des travaux de ce savant industriel, et ont reçu tous les renseignements qui pouvaient les intéresser. Il est probable, ont-ils dit, qu'à leur retour le gouvernement français lui demandera un de ces grands instruments dans la fabrication desquels il excelle.

Les savants français se sont ensuite dirigés, accompagnés du fils de M. Clark et de M. Appleton, vers l'observatoire de l'Université de Cambridge. Le directeur de cet établissement, M. le professeur Pickering, était malheureusement absent; mais M. Clark et M. Trouvelot, astronome français, attaché à l'Observatoire, leur ont montré tous les détails du beau cercle méridien de l'institution et de son grand équatorial.

A deux pas de là, MM. André et Angot ont été reçus par le grand poète américain, Longfellow, qui insista gracieusement pour leur faire accepter une collation. Malheureusement il leur fallut bientôt se soustraire à l'aimable compagnie de ce beau vieillard, qu'on ne peut approcher sans être pénétré d'un profond sentiment de vénération, pour se rendre à l'Université de Cambridge (Harvard College). Le président, M. le professeur Eliot, les attendait, et leur a fait visiter toutes les parties de cet établissement, l'une des gloires de ce pays.

Cette visite était d'autant plus intéressante pour nos compatriotes que la France fait actuellement de grands efforts pour renouveler son enseignement supérieur. Une société particulière, libre de toute attache officielle, y a été tout récemment fondée par des hommes libéraux avides de progrès, et, dans le but d'accélérer ce mouvement de rénovation, les recherches dans chacune des branches les plus éminentes dans le domaine de l'instruction publique. M. le président Eliott a été invité à devenir membre correspondant de la société, et nous sommes heureux d'apprendre qu'il a accepté ce titre.

Le lendemain a été consacré à des visites aux musées de Boston, qu'on appelle justement l'Athènes américaine, et au fameux *Soumerset Club*, le plus beau des Etats-Unis.

Dès leur retour à New-York, MM. André et Angot ont bien fait leur trop court séjour en Amérique; ils ont visité à *Menlo Park*, où ils ont été admis à visiter le laboratoire désormais historique de célèbre Edison. Ils sont revenus émerveillés des prodiges que leur a montrés ce jeune homme de génie, et aussi de la simplicité modeste avec laquelle il expose les plus brillantes et les plus étonnantes découvertes.

New-York Daily Tribune.
FOUNDED BY HORACE GREELEY.
SATURDAY, JUNE 8, 1878.

An interesting letter from Mr. Edison, on another page, sets forth the grounds on which he claims priority in the telephonic inventions which Professor Hughes has recently exhibited in London. It must be granted on all hands that the discoveries of Mr. Edison suggested the line of experiment which led to the invention, and it may prove difficult to draw the exact line at which the English instrument can claim any originality. As a whole, however, it is of simpler construction than previous telephones, and Mr. Jacobs, according to the accounts furnished, to have more remarkable powers. The most striking feature of Mr. Edison's letter is his statement that he has been betrayed as to those inventions by a person who was the agent for his telephone in England. Considering the provocation, Mr. Edison writes with remarkable moderation and dignity. He may be sure that the scientific world will see, to it that he is robbed of some of the laurels he has so honorably and conspicuously won.

TELEPHONE AND MICROPHONE.

LETTER FROM THOMAS A. EDISON.
THE QUESTION OF PRIORITY OF INVENTION.
HOW HIS AND PROFESSOR HUGHES'S DISCOVERIES CONFLICT—EDISON CLAIMS A VIOLATION OF HIS RIGHTS, AND A BREACH OF CONFIDENCE BETWEEN FRIENDS.

To the Editor of The Tribune.

SIR: Allow me to make a few observations upon an editorial article which appeared in yesterday's TRIBUNE upon the recent claims advanced by Professor D. E. Hughes, of London, in his invention of the leading features of my carbon telephone, and of my microtransmitter or instrument for the measurement of minute degrees of heat.

You have attributed to Professor Hughes two improvements upon my method of procuring the electric battery for the telephone namely: In the installation of the carbon by plunging it in mercury, and in the division of the carbon into several pieces. I can appreciate that the latter process is not identical with my use of one short carbon, but perfectly correct, but the substitution of the carbon had been repeatedly tested by me in my experiments on the telephone, especially in a series conducted at the special request of President Orton shortly before his death, at which the illustrative drawings were seen at the time by several persons, and are still in my possession. The substitution of the carbon by plunging it in mercury is also a process perfectly familiar to me, having been employed in many of my telephone experiments of last year, and, though mercury is not specially named, it is clearly included in the expression "finely divided metals" which occurs in the second paragraph of "The Speaking Telephone," as printed in "The Journal of the Telegraph for the 16th of April last. Mr. Hughes seems to have been so impressed with this phrase that he employs it repeatedly, speaking of "mercury in a finely divided state," of "holding the mercury in a fine state of division," of "metal distributed—in a fine state of division," of "iron in a fine state of division," again, of "the minute division of the iron," and lastly of "a platinum surface in a finely divided state."

The change of electrical resistances with enormous rapidity by plunging under pressure was a discovery of my own, distinctly set forth in my application for a patent for an "improvement in speaking telegraphs," dated July 20, 1877, as published at the time in *The Philadelphia Press* and *The Scientific American* (July 28, 1877). This discovery evidently covers the principle claimed as his own by Professor Hughes. He says: "It is quite evident that these effects are due to a difference of pressure at the different points of contact"—which is precisely the principle of my carbon telephone, therein set forth months ago by Mr. Gen. R. Prescott in the above-mentioned column. My statement expressed meaning, however, Mr. Edison at length made the discovery that when properly prepared, carbon possessed the remarkable property of changing its resistance with pressure, and that the ratios of these changes, however, corresponded exactly with the pressure."

You continue as the most striking difference between my telephone and the instrument of Professor Hughes, that in the latter the diaphragm is dispensed with. In his own words, "it will be seen, however, that in the experiments made by myself, the diaphragm has been altogether discarded, resting as it does upon the changes produced by molecular action, and that the variations in the strengths of the currents flowing are produced simply and solely by the direct effect of the sonorous vibrations."

The following extract from Mr. Prescott's book, as given in *The Journal of the Telegraph*, April 16, 1878, will show that the discarding of the diaphragm is my own invention:

In its naked form of transmitter with Mr. Edison has introduced, the vibrating diaphragm is done away with altogether, and the carbon is made to receive the vibrations of the sonorous waves directly, as the vibrations after having been once started. In the new arrangement, now described, the carbon is made to receive the vibrations of the original sound waves directly, by the intervention of neither diaphragm nor membrane. The telephonic plate, of carbon, merely serves, in connection with the battery, to modify the waves in consequence of the molecular motion of the carbon to which it gives rise. The small carbon disc or button, a ninth of an inch in diameter, is made to receive the greater degree of motion for the reason that the whole face of the speaker is thus exposed to the vibrations, and can consequently be affected by the small surface atoms more than could be obtained if only the small surface alone were used.

The claim of Professor Hughes to the discovery that the installation of his microphone can be used as a measure of minute degrees of heat is still more preposterous than the preceding. This is a discovery of mine, which was first announced in *The Washington Star* of the 19th of April last. A copy of that *Star* of the 19th of April last. A copy of that *Star* was sent by me to Mr. W. H. Preece, the correspondent of Professor Hughes in this protected adjuster of Professor Hughes in this protected adjuster of Professor Hughes in this protected "invention," and I have positive evidence that it reached him before the presentation of the so-called "microphone" to the Royal Society. I transmitted as he has made an address from it to the address of May last before the London Society of Arts.

Mr. W. H. Preece, electrician to the London Post Office Department, was in this country at the early part of last year, and visited my laboratory. I freely showed him the experiments I was then making in connection with the carbon telephone and the variability of conducting power in granular substances under pressure. I made application for the protection of the telephone, and almost exactly of the phonograph, in England, and four months before the publications and by private letters, describing experiments, as he always manifested a great interest in the progress of pneumatic my discoveries to his friend, publicly.

I therefore regard the conduct of Mr. Preece in this matter as not merely a violation of my rights as an inventor, but as a gross infringement of the laws of international comity, under the guise of friendship.

Yours very truly, THOMAS A. EDISON.

Menlo Park, N. J., June 6, 1878.

The Sun.

SATURDAY, JUNE 8, 1878.

EDISON'S "EAR TELESCOPE."

THE BELIEF THAT THE INVENTOR IS PREVENTED FOR THE DELIV-

Conversation Carried on with Ease Between Persons Two Miles Apart—A New Device that will Enable Doctors to Detect Disease.

Upon his latest discovery, which he hopes to utilize principally for the deaf, Edison has not given much thought for a few days. He has had something else in mind. An unusually large number of persons called on him at his laboratory in Menlo Park yesterday, and they found him very busy upon experiments with carbon. His hands were as black as soot and there were smudges of grime all over his face. With an electrical pen, from which he thrust little pins, he cemented different substances to carbon, and then tested the resistance and heat, denoting the power of each kind of carbon to break resistance.

He was solid at him a workmen talked nursery gossip in a phonograph as a matter of business. On the table there stood a telephone, a phonograph, a microphone, and a number of batteries. Over will hereafter be known as the "Edison table." Near one end of it was a little box with a mouthpiece and a receiver at the end of the laboratory, and Mr. Barkelew was talking to Edison through it.

"Now, Barkelew, I am going to walk to the end of the room and whistle."

Mr. Barkelew put his ear or pistils on dit Mr. Griffin, who stood at the other end of the room, and whistled some tunes, which Edison, in the laboratory, could hear and recognize. The telephone might be used as a telescope for the deaf, Edison thought, and the practical question was how was the most perfect piece of work ever done with the telephone," said Edison yesterday.

Standing against the table that supports the telephone were two instruments almost identical in appearance. Each consisted of a wooden box, about a foot square, with a mouthpiece to hold a piece of hose. "Now, Barkelew," we heard Edison say, "you have a piece of the rubber hose that connects the mouthpiece with the receiver. Put it in your mouth and speak as if you were talking to me. That isn't the name. I mean that piece of hose. Now, Barkelew, will I be talking to you by way of the telephone, or a speaking-tube simply? Now, I want you to tell me what I am saying. Don't look here." And Edison, who had turned away from the table, now put one ear to the mouthpiece, pointing to the little end. "You have always outside dinner when you did before."

Edison it was so, and no pistols as to torment him.

"But that one is no good," he said, "for this purpose. This is the one, and I have got the receiver with me. Now, Barkelew, talk."

He heard part of the logical former, and took up one somewhat smaller. It was made of three pasteboard boxes, and was nearly like a large

"That's about all there is to it," he said.

"But what is it going to do?" the reporter asked.

"Well, I wanted some simple, convenient thing that deaf people can use in a theatre, church or anywhere, I had an idea that might, perhaps, be developed for their service, by catching the vibrations of their voices. Once I could carry them into electrical current, they might be sent to a man's ear or by sight. From this start there might be developed an instrument that would enable the deaf to hear, and just how to reach the useful situation."

Then Edison sat on the table, and, swinging his feet, talked about the telephone, the phonograph, and kindred matters. He said that the truth: and Mr. Griffin, his old time fellow-workman, and Mr. Barkelew, manager, remained motionless, and were evidently interested in the mental operations and scientific discussion. Edison said he had to do all his inventing.

"Do you, sir, sound be produced like this?" Mr. Griffin asked, as he put his ear to the receiver, do when you want to get that from a distant object, or if your eyesight is bad, to get closer to the instrument?" "Why, you see, when the ear is not in use it will work and you can hear the vibrations of light."

Graphic June 8. 1878

EDISON'S PHONOGRAPH IN PARIS.

WHAT THE SCIENTISTS OF FRANCE SAY OF THE TALKING MACHINE.

THE DAILY SEANCES GIVEN ON THE BOULEVARDS—A FRENCH INVENTOR'S GLADE.

[Correspondence of The Graphic.]

PARIS, May 25.—All about the gayest part of the gay boulevards, amid the throng of strangers of the fabulous at the cafés and the crush of amusement-hungry promenaders who seem to have not an idea beyond what they shall eat and what they shall buy, there may be seen every day and several times a day groups of thoughtful-looking men and women, attending their way to a small hall—in Edison Cancellor's time the back of a convivent of an impending house on the boulevard of that name, where lectures concerning the Electric Telegraph and Illustrations of its working are now being given, for the first time in the French metric, to the public. The greatest sensation in Europe is Mr. Theodore Puskas's, as yesterday I had the pleasure of a personal interview with the gentleman. In the first place, let me say that Mr. Puskas seems to me the man of all others to whom it was wise that this important theme should have been entrusted. "The selection was a happy one in all respects, and Mr. Edison is to be congratulated upon it. Profoundly impressed with the marvellous character of the invention, thoroughly conversant with all its details and those of all instruments in any way similar to it, Mr. Puskas possesses the power of clearly explaining, both in English and French, the workings of the wonderful invention. Yesterday afternoon I was present at a seance at the lecture hall, and after the wonderstricken audience had departed, Mr. Puskas kindly addressed me what the phonograph had been doing in France.

"The truth now of science have been astounded at the latest of the accomplishments of the seven-times marvellous," said Mr. Puskas, "and at first when the powers of the phonograph were announced the universal cry was that there was something which could not be done. But after a time, when the phonograph fulfilled every claim that had been made for it, then a voice arose and said: 'Yes, quite so; I discovered the telephone!'"

"A claim to priority of invention of the phonograph by a Frenchman?"

"The priority of the idea of an instruments which would record the sounds of the human voice, though no such instrument ever was made, and it is highly improbable one ever will be made according to the present conceptions."

"Who is the person who had this idea?"

"Mr. Cros, Ex-President of the Academie des Sciences Occultes. His remarks preceded the first exhibition in the Palace of Electricity, Rue Rivoli. Mr. Cros deposited at the French Academy a sealed paper describing an instrument of which he had an idea, to be called the paleophonograph."

"Did you respect did this idea resemble Edison's?"

"Only to the extent of the notion of a machine repeating the sounds of the human voice. Mr. Cros had no conception whatever of the use of the tinfoil in the instrument. His plan was to make use of Scott's Phonautograph, and upon the cylinder with epinam a hair or a feather or something else that, very delicate and fine. This hair, moved sensitively by the air waves of the voice, would trace on small lines on the lampblack, and these lines Mr. Cros proposed to photograph or by a known process. At the end of a certain length of time and various processes the lines would be found. The idea of instantaneous reproduction was not at all entertained by Mr. Cros."

"Then you do not consider the construction of an instrument in accordance with Mr. Cros's ideas possible?"

"I have the opinion of M. Koenig, the celebrated instrument maker and inventor of the forms of singing flames," replied Mr. Puskas, "that it is thirty thousands Mr. Cros could ever construct an instrument which would work practically. He could not hear it in ten years, and he so master a satisfactory result was to see Edison."

"I understand that you have had an exhibition of the phonograph before that mutual body of learned men, the French Academy of Sciences."

"Yes, and on the occasion there was a great triumph for Mr. Edison, for the members *absolutely refused* to believe the statements of their senses. They thought I was a ventriloquist, and was using that trickery to obtain the results which astonished them. Accordingly, they requested me to leave the room that one of themselves might sing into it. After the conclusion I test the *across* were as crucial in their properties as they had previously been cautious in their suspicions. The warmest admiration was expressed for the great American inventor, and the hearty thanks of the body were sent to Mr Edison."

"I hear the wonder worker is coming to Europe this summer," I said.

"I think he will be here before the Exposition closes," replied Mr. Puskas. "He said he thought he should come to-day. I hope he will for his own sake. As hearty a reception as ever was accorded to a man of science awaits him at the hands of the *savans* of France, and if he comes he will receive a meeting of which any nation on earth would be proud."

In the financial *across* the phonograph is a decided success on the boulevards. Three *seances* a day are held, morning, afternoons and evening, at prices of admission varying from three francs to one, and an average of $200 daily is received at the doors. The hall has been secured for three months, and it is inevitable, with the additional notoriety the phonograph will receive every day receiving, that the vogue of the *seances* should go on increasing, and that crowds greater and greater in number should gratify their curiosity concerning the phonograph. Scarcely a day passes that the inventor is not requested to have a private *seance* of the phonograph given at his or her residence. Yesterday I noticed by M. C. Rosenvi, one of the old and distinguished family, whose name is a synonym for wealth and respectability in New York, Mr. Puskas a short time ago, took the phonograph to the Palace of the Elysee and demonstrated its power in the presence of the Marshal-President and a brilliant assembly. The Marshal was exceedingly interested in the workings of the instrument, and expressed himself astonished at the successful recording, and the *seance* was given at the splendid hotel of the Princess Mathilde, in the Rue Rivoly Cleis, the Cercle Agricole, the Salons of "Encouragement and the Societe de Physique, and in many other establishments, have exhibited the phonograph, and said "it was passing strange."

The phonographs in use on the boulevards were made in France, as the importation of foreign-made instruments is not within the French *invest*. One is Edison's, for cylinders, with cornucopia-like trumpet and a tinning cranks; the other is a later improvement, a, a brass mouthpiece cap and the crank at the end of an elbow. On the boulevards the latter and the first are in use, of course, given in French; and sometimes, when the *auditoire* comes of a class of the businesses there is a smile at the thought of this little iron thing, the phonograph, fiercely using a language with which its maker, Edison, is probably quite unfamiliar. Could you but hear the effect of what superb ease and accuracy of *accent* is pointed out its own praises in the following sentence:

"Le phonographe est un instrument merveilleux! Il reporte tout ce-que-l'on lui dit. Au revoir!"

Students of any foreign language will make use of a phonograph to correct them in pronunciation, and every country required some native to utter a few sentences for it. The irrepressible French *figure* is responsible for the following, given that, a fatuity of distinction, having uttered that, a fatuity of fatuity, turned on their phonograph-cylinder, and, to the astonishment of the great many successful times it stood, threatened to have the instrument taken into the instrument with the remark that it was the most wonderful phonograph has been allotted space in the Exposition.

"Well, but to see you on view there, and it is not likely that you will be allowed to remain there for three or any time. The reason is evident, as soon as the phonograph can accept a paying notice on the door of the hall. In the interest of those who had the right to it in France to show it gratuitously at the Exposition.

NEW-YORK, SUNDAY, JUNE 9, 1878.

THE PHONES OF THE FUTURE.

Since the philosophic Franklin first got the lightning "on a string," the ingenuity of man has put the subtle and all-pervading fluid known as electricity to such various uses. In opposition to the ordinary methods of education, he first set it to writing, and having developed its faculty in that direction to the utmost, he has at last taught it to speak with most astonishing organs. It not only reads its own writing, which is more than some lawyers and stenographers can do, but it will gather up the stray *accents* that are floating in the air and give them concentrated utterance. So it is that the era of phones is succeeding the era of graphs through the connecting link of the phonograph. That is as yet scarcely begun, and it is impossible to predict the results of its development. Thus far we have the phonograph, that both reads and writes and harmonizes all the vocal music; the telephone, that transmits sounds over long distances and spectinulates them at the far end of the line; and the microphone, that magnifies them by many diameters. What other phones await us it is early for human genius to tell, but there can scarcely be a doubt that electricity is destined to give us a complete mastery over all the sounds of nature.

Already we have an inkling of what we may expect. The voracious man of science tells us that we may hear the pressing of a fly as a mutable click with all the distinctness of a horse clattering over a bridge in the neutral of Venice's famous line.

Quelquefoste porous audis quasi sapide cerique."

Even the insect's respiration may be clearly heard like the wheezing of an asthmatic elephant. Soon we can bring equidistance to bear to gather up the minutest sounds, magnify them in tremendous volume, and hurl them to any desirable distance. We are assured that we shall be able, not only to listen to the tramp of the distinct insects, but to hear the growing of the grass and the ripple of the sap ascending by earth the tree. We shall be able to catch with the magic alchemy in the laboratory of the leaves; we may increase the greatness of earth and air into forms of beauty, and all the bravery of the Summer's green shall become audible as the elatter of a common workship. Then will the dreaming poet, as he lays him down to the woods or field to feel the thrill at nature's voice, command himself with histories, dales, and wires, and bring to his ears the clash and roll, the boom, the rhythm and the clang of a Titanic orchestra. Nor will it be necessary to go to the fields and subject one's self to the dependence of bees and ants to get all the benefit of the magnified and multitudinous sounds that keep the atmosphere vibrating. They may be gathered from their haunts in field and by brook, and the glees of forests and along the sounding shore, and be brought by wire from every direction to some grand hall in the busiest metropolis, and there let loose for the edification of gathered crowds. Furthermore, instruments may be devised whereby these myriad notes may be commingled and controlled to the utterance of most excellent music. Who knows but even the music of the spheres, the voice of the smallest star that

147

"is its motion like an angel sings,
Still spoking to the young-eyed cherubim,"

may be made perceptible to mortal hearing. The voices of earth and heaven may perchance unite in one tremendous symphony through the agency of the symphone. Man is yet to be invented.

But there are other possibilities hardly less interesting. Not every sound, whether of nature or of art, is either soothing or exhilarating. The nerves of man are subject to tortures as well as exultations. It is not given to all persons to be gently

"Stalled with buming night-dies to their slumber,"

and to sense the shrill clarion of the mosquito on his midnight intendilize is anything but soothing. Cats that make night hideous with their private wrangles, and scolding poultry that spoil the morning nap, these utter sounds that no one would wish to have magnified. And though there might be a cacophone devised as an instrument of torture, to be used, perhaps, as a means of punishment for the worst, class of criminals, as something more terror-striking than death itself, yet the virtuoso and humane would be more concerned for some opposites that would utterly destroy and nullify horrid and distracting sounds. For casual humanity to apply itself to conserving some means for eliminating discordant noise from the air and so that the cat on the back fence, with arched back and tail erect, may be "mum and not heard," and the mosquito quench his raging thirst for gore without accompanying the victim with his whining, exhilarating cuticles. And while the combined telephone and microphone might, in the household, enable one to gather up scent interesting whispers and accurately pump the pulsations of two hearts that beat as one, it would be a peculiarly precious boon to be able to sit in one's study all accustomed of noises sounds. The strident and indirect upbraidings of the motherin-law, the peevish cry of other people's children, the heart of buzzpetty passerby, the din of hand-organs in the street or piano in the adjacent boarding-house, and all the distracting noises that make the misery, might be smothered by a faithful anti-phone of some sort, whose function it should be to take the life out of every intruding sound. But no volume of mechanic contrivance would suffice for the setting forth of all the possible results of the invention of phones and their application to the assimilation of sounds. "We can only give the imagination a hint, and let it rove in this new, fascinating field, and speculate on some avail the *slow* processes of invention before a full realization of the benefits of the latest sons of electricity.

PHILHARMONIC CONCERT TONIGHT.

THE ENGINEER. MAY 24, 1878.

THE SOCIETY OF TELEGRAPH ENGINEERS.

THE TELEPHONE AND MAGNOPHONE.

On Thursday evening a special meeting of this Society was held to hear a lecture from Mr. W. H. Preece, on the recent discoveries of Prof. D. E. Hughes. As we gave an account of the investigations of Prof. Hughes in our last issue, it is needless for us to recapitulate the experiments. It will suffice therefore to say that the lecturer, who really possesses a talent for description, vividly described to a large audience, the gradual opening out of the discoveries, and the way in which they had been followed up by many beautiful experiments. Prof. Hughes's quiet modesty proved that the sciences (theatrical laughter and electric conducting matter—for aught he finds that in the glass tube transmitter—see cut—it is the glass tube which is really subjected to the vibrations.

At the close of the able lecture's short discussion followed, by the simple expedient of avoiding the inventiveness of heavy W. H. Scott had the opportunity, so far as we can gather at present, obtained results similar to those obtained by Prof. Hughes. In speaking of his experiments, Mr. Scott says:—"Omitting all needless details, it may be briefly stated that my first distinct impressions upon the ordinary magneto-electric telephone were obtained by modifying the diaphragm or vibrating armature of the instrument; thus it was of course quickly found that the smaller the portion, the greater the weight of metal caused to vibrate for a given sound, the greater was the strength of the sound emitted at the "listening end," although frequently at the expense of clearness. Increased definition, however, I may be allowed to impart a convenient optical term—was obtained by the simple expedient of avoiding the inventiveness of heavy and therefore more rigid diaphragms, by employing a number of soft iron in place of one thick plate, and this arrangement is still a practical improvement that instruments provided with five small armatures, of the same four having central eyes—will receive and emit nearly twice a variety of sounds for which in the ordinary "Bell Telephone" there is simply "no thoroughfare."

Even several armature-plates to a considerable number would be required to produce the fine effect produced on each of these coils are farthest from the magnet. Reasons we shall, therefore, think are furnished for using sometimes a vehicle current to further exalt the effect—for multiplying the number of armatures without, at the same time, increasing the weight or inertia of the mass to be moved, and always with advantage until it was found that the most sensitive armature for the receiving instrument that acted in the form of powder or filings. It is not too much to say ten grains of soft iron filings, affixed by suitable means to a paper diaphragm membrane, are capable of producing further results than forty grains in the shape of a "ferrotype disc."

On carefully localising the vibratory sensations of the transmitting telephone, however, and including it in the circuit of a battery and apparatus, which, as at present, is usually pitted to one end, a phenomenon which still obtained when the "iron filings" or previously described was employed. The whole of these experiments were performed with instruments somewhat roughly put together, and consequently pitted to about semi-tone, and it was after carefully discovery step-forward that seemed to have been made when I discovered that by simply substituting the transmitter "string such good results had been obtained, and had slipped about an inch and a half away from the diaphragm, being therefore entirely out of contact with it, from that point of view. The fact that its entire removal did not affect the intensity of the instrument occasioned me, however, but little additional surprise.

It was impossible to avoid believing that here might at last be found the true cause of a variety of phenomena hitherto unrecognised, but which have been observed by numerous experimenters in a more or less freely divided condition were introduced into the circuit in connection with "transmitting telephone," whose conductivity—or "resistance," as ordinary electricians would say—was impossible to the most sensitive wheatstone bridge and "galvanometer," for transcending in delicacy any instrument yet devised.

If other platinum, mercury, or silver—and doubtless other metals in a different degree—were subjected to an extremely fine state of division within the cavities of suitable porous substances, such as pumice-stone, asbestos, &c., similar results to those above mentioned may be formed. Therefore, while carbon appears to act in a favourable degree; by their all the same, a shaker's diamond is "brilliant" well, without any great stretch of imagination, it might be taken for the distant reverberation of a "rustle" in some night's "Scotch mist." Or, "hum" of a mimic

Dr. Nolan, in faithfully transcribing the general appearance, to the eye, of these curves, was of course not able, in the limited time given, to preserve the absolute thicknesses and lengths of the curves, as indicated in the records in the Proceedings of the R. S. So, in the former, the letters A, E, I, O, U, and OU (Webster), I and U are much alike in general form, as also are A and O, the complete of the pairs of the latter being the most striking features; O and A, in the shaders, look about the difference in shape produced by less intensities, the short being drawn out, and more acutely. O I is very interesting. The diphthong consists of O, and the very muscle which characterise the transition from one vowel to the other. It is a very complete character, but its derivation has not yet been made out.

The above presentation of the subject, is necessarily crude and imperfect, but will illustrate the possibilities of an exhaustive investigation. It should be added that Professor Alfred Mayer has published, in the last number of the *Popular Science Monthly*, a representation of the curves made by the clay "bell," and a comparison of them with the curves of the vowel sounds, and with the curves of the Koenig tones, when actuated by the same sound

[Note.—In the woodcut the forms made by the curvatures of the styles for the short letters are wider than they should be.]

* Franklin Institute.

EXAMINATION OF THE PHONOGRAPH RECORD UNDER THE MICROSCOPE.*

By Professor Fleeter, Jr., A.M.

At a meeting of the Philosophical Society, held April 5th, 1878, I described the results of experiments made with the tinfoil which had been indented by the stylus of the phonograph. My object was to ascertain the action of the stylus in cutting the wave forms corresponding to articulate sounds. For this purpose the superintendent of the Philadelphia Local Telegraph Co. kindly placed at my disposal the tinfoil upon which diphthongs were spoken. With the assistance of Wm. Weeks and with small panels in the mouthpiece of the apparatus sounds were repeated thirty-six times, the diagram. These then mounted on glass plates, separated, and the tinfoil cut off at the suggestion of Mr. Knight, the plates were cut out and mounted on another piece of glass vertically, instead of horizontally, in which position the number of the drops produced by any given sound could be seen between at once. I am much indebted to Mr. Holmes for his kindness in adapting the apparatus, which he himself will explain a little later, to the purpose of showing these phonographic records.

Lieutenants Leon Smith, and Greely have provided the means of transferring sounds into form, in various ways, viz.:—By bright lines on the ends of short bars of different thicknesses; by vibrating membranes at the extremity of a "phonautograph," and by the indentations of a revolving mirror. It was natural to conclude that the same vibrations, imparted to a steel point by means of a metal diaphragm, would produce an equally characteristic trace. It was intended to take a number of these depressions in Canada balsam, or some other transparent medium for examination, but this, on the minute eye, the path of the stylus point. There had not been time for this. The same video [illegible] as nearly as possible at the same distance from the mouthpiece, was rolled on the cylinder of the instrument.

The first records, tried to ascertain whether the pronunciation was perfect, were afterwards thrown away, and the best of those were studied were not in any way injured by a second passage of the point of the stylus. By following along the nearly vertical lines, corresponding to which are at the same time in focus, it will be observed that the fine outside of one long followed by two short—or two short followed by one long—the indications being a general resemblance to each other and to reeds. This is a long A, or "Ah." A glance at the diagram will show—still above the same thing, but the overlapped hollows are narrower, and there are no abrupt terminations of the hollows by intersection with the side of the foil which have not been touched by the needle point—or say—on the screen, looked like the magnets of two bells (electric) which have small coils turned towards each other. In the diagram they look like two Indian clubs with the handles together. The same general appearance is observed in the O short, except that, as in a short, the volume is much less, the intensity was less, or—which is the measure of intensity—the path of the needle point was shorter, and it seldom entirely severed the foil; the consequence being a continuous groove of [illegible], but normally irregular, width.

Phonographe, Téléphon. Phonostographe, Plume électrique.

Si l'ancienne vieille encore, quel admirable autonome il pourrait construire, grâce aux découvertes de la science moderne! Ce ne serait plus un simple joueur de flûte qu'il offrirait aux regards du public émerveillé, mais un véritable ventriloque, un chanteur automatique. Un Américain, M. Edison, est, en effet, parvenu à faire parler la matière, à lui faire retenir chants et discours.... Dès le début, quand l'inventeur a présenté son phonographe, il a trouvé bien des incrédules, même dans le monde savant; nous pourrions même dire surtout dans le monde savant. La prétendante américaine de la nouvelle découverte était peut-être déjà une raison pour exciter la défiance; — l'Amérique a tant de fois mystifié l'ancien continent! — et l'on était assez porté à croire que toutes les prétendues merveilles des phonographe se réduisaient, en somme, à d'habiles effets de ventriloquie. Il était vraiment permis d'être incrédule, car on avait devant soi un instrument qui venait démontrer une fois de plus que souvent la pratique devance de beaucoup bien souvent la théorie. Voici, d'une façon sommaire, la description de ce curieux appareil :

Le phonographe se compose d'un tympan destiné à transmettre les sons et d'un cylindre dont le rôle est de les inscrire.

Le tympan consiste dans une feuille métallique très-mince tendue à l'extrémité d'une embouchure de bois. Au centre de ce tympan, et perpendiculairement à lui, se trouve fixé un style d'acier très-court supporté par un petit axe en caoutchouc.

Le cylindre récepteur est en cuivre; il porte, gravée à sa surface, une rainure hélicoïdale d'environ un millimètre de largeur et qui va d'une extrémité à l'autre. Il est, de plus, traversé par un axe à vis, le long duquel il se meut et dont le pas est exactement égal au pas de l'hélice. Cet axe est muni d'une manivelle qui permet de le faire tourner. A la surface du cylindre, on applique une feuille d'étain, semblable à celles qui servent à envelopper le chocolat, en ayant soin que cette feuille soit parfaitement lisse et ne présente aucune aspérité.

Lorsqu'on veut se servir du phonographe, on fait tourner le cylindre jusqu'à ce que l'origine de la rainure se trouve en face du style du tympan, de façon que ce style puisse suivre constamment la rainure que creusera la feuille d'étain. On parle alors dans l'embouchure en même temps qu'on tourne la manivelle d'un mouvement régulier. Le style, en vibrant sous l'impulsion du tympan, trace alors à la surface de la feuille d'étain, qu'il enfonce dans la rainure, une série de dentelures représentant non-seulement l'inscription des sons, mais aussi l'articulation de la parole. Voilà donc le discours (ou le chant) inscrit avec son intensité et ses modulations. Pour le faire rendre par l'instrument, on procède de la manière suivante :

On ramène le cylindre à son point de départ exact, de façon que la pointe du style se trouve en contact avec l'origine des dentelures, et on commence à tourner après avoir placé dans l'embouchure un cornet de carton destiné à amplifier les sons et à jouer le rôle de porte-voix. Le style repasse alors par toutes les dentelures qu'il a tracées la première fois et transmet à son tour au tympan les vibrations que celui-ci lui a communiquées d'abord, de sorte que la phrase inscrite se trouve rendue automatiquement.

La semaine dernière, nous avons assisté à une séance de la Société d'encouragement, au cours de laquelle M. le comte du Moncel, membre de l'Institut, a fait sur le phonographe une conférence fort intéressante. Il a rappelé que si le phonographe est d'invention américaine, l'idée première de cet appareil appartient à un Français, M. Léon Scott, qui, en 1857, prenait un brevet d'un tour en tournant qu'il appelait phonautographe. Ce phonautographe se compose d'une caisse de bois en forme de pyramide tronquée, ouverte à sa base et revêtue à l'intérieur d'une épaisse couche de plâtre destinée à empêcher les vibrations de la paroi de la caisse. Le sommet de la pyramide est fermé par un tympan en forme de tambour et dont les membranes sont composées de trois tuniques; deux en caoutchouc et une tunique centrale en baudruche. Les deux membranes sont tendues par un petit appareil en ivoire destiné à jouer le même rôle que la chaîne des osselets dans l'oreille humaine (voir fig. 2 bis) et qui augmente de beaucoup la sensibilité du tympan. Lorsqu'on chante dans le conduit, les vibrations de la voix sont transmises au style qui les écrit en bleue sur un cylindre tournant recouvert d'une feuille de papier sur laquelle on a déposé un petit nuage de noir de fumée

L'appareil a donc enregistré donc déjà les vibrations; le phonographe a fait un pas de plus, puisqu'il inscrit l'articulation des sons; mais un pas dont que celui-ci est le fils de celui-là, ou du moins qu'il existe entre les deux appareils des liens de parenté très-proches.

Reste donc à la séance de la Société d'encouragement. A nous avons vu fonctionner le phonographe Edison. Les résultats de l'expérience ont été très-satisfaisants. Cependant, il y a certains mots que l'instrument rendra plus facilement que d'autres, ceux où il y a des r, par exemple; aussi l'expérimentateur choisit-il de préférence des phrases ainsi construites de mots.

Le phonographe a très-bien redit la phrase suivante : « Le phonographe a un très-bonne mémoire; il ne rappelle tout et il le répète. Hourrah! hourrah! »

Tandis qu'il a articulé d'une façon bien moins distincte les deux phrases anglaises suivantes :

« *How do you do, Sir? How do you like the phonograph?* »

Les quelques imperfections de l'instrument sont disparaître, pourtant, et avant peu, M. Edison doit exhiber un phonographe parfait. Étant donné la véritable génie d'invention de M. Edison, nous ne doutons pas qu'il parvienne aisément à remédier aux légers défauts de son appareil.

Puisque nous nous occupons aujourd'hui d'instruments d'acoustique, parlons aussi du téléphone, que tout le monde connaît déjà de réputation, mais que tout le monde ne comprend pas.

Le téléphone repose sur la propriété que possède un barreau aimanté de produire un courant induit lorsqu'un approche d'un de ses pôles un morceau de fer ou d'acier. L'appareil se compose d'une embouchure E, d'un tympan T, au-dessous duquel se trouve placé, à une petite distance et perpendiculairement à lui, un barreau aimanté A, muni à sa partie supérieure d'une bobine B. Autour de cette bobine est enroulé un fil métallique extrêmement fin entouré d'une enveloppe isolatrice de soie. Les deux extrémités de ce fil sont rattachées à deux conducteurs destinés à mettre en relation deux téléphones. Lorsqu'on parle dans l'embouchure E, le tympan en vibrant se rapproche plus ou moins du barreau aimanté dans lequel il détermine un courant induit plus ou moins énergique, selon que les vibrations sont plus ou moins intenses. Or, comme tout le téléphone récepteur où se produit un mouvement moléculaire spécial appelé mouvement magnétique. Quel, maintenant inappréciable, est suffisant néanmoins pour faire vibrer la couche d'air qui sépare l'aimant du tympan, et, par suite, le tympan. En appliquant l'oreille contre l'embouchure du récepteur, on entend donc distinctement les paroles prononcées à l'autre extrémité du fil.

A raison de la faiblesse du courant induit, la distance à laquelle le téléphone peut transmettre la voix est relativement restreinte; mais on a cependant obtenu des sons perceptibles à une distance de 100 kilomètres, ce qui constitue déjà un joli résultat.

A l'heure qu'il est, un inventeur français croit avoir trouvé le moyen d'écrire les dépêches téléphoniques, et bientôt probablement le téléphone recevra un complément qui lui est nécessaire.

Après avoir décrit le phonographe de M. Edison, M. le comte du Moncel a fait connaître à la Société d'encouragement une autre découverte du fécond inventeur américain, la plume électrique.

La plume électrique, dont nous donnons le dessin, consiste en un petit appareil électro-magnétique renfermé dans une cage métallique et fixé au sommet d'un tube en plume terminée en pointe à son extrémité inférieure. L'électro-aimant est fixe et, devant ses pôles, tourne une lame de fer doux formant le diamètre d'un cercle d'axe qui joue le rôle de vilebrequin et peut exécuter environ 3,000 révolutions par minute. L'électro-aimant est relié par deux fils conducteurs à un petit élément Bunsen, qui produit le courant dans l'appareil.

Au volant est adapté un excentrique qui imprime un mouvement de va-et-vient à une aiguille renfermée dans le corps de la plume, qu'elle traverse dans toute sa longueur. L'aiguille se trouve donc, par un mouvement très-rapide, successivement ramenée en dedans et projetée en dehors; elle perce ainsi dans la feuille de papier sur laquelle on la promène une série de trous extrêmement fins qui constituent un véritable pointé. Il faut avoir soin de placer le papier sur une surface flexible, un morceau de feutre ou de papier buvard, par exemple, afin que la pointe pénètre le papier et ne s'émousse pas.

Lorsque la feuille est écrite, elle constitue alors un véritable cliché. On la place donc un châssis qui la maintient sur la planche d'une presse destinée à tirer les épreuves. On met alors en dessous une feuille de papier blanc, on rabat le châssis et l'on passe sur le cliché un rouleau de teinte chargé d'encre d'imprimerie à laquelle on ajoute un peu d'huile pour la rendre plus fluide et lui permettre de pénétrer plus aisément dans les trous du cliché. L'écriture ou le dessin

Toujours ces mêmes femmes ! — Ah ! mon ami, si je savais...
Si de la cotte sans..... on avait vu le tort, —
Plus que la coiffeuse, fournissant adultère,
Je transporte les nom par un tout petit côté. —
Et moi, qui sais pour, ne me voit cependant
Par mon faire figurer dans le mot précédent. —
Ah ! si j'avais seulement pu me faire tailler,
Au soleil trop ardent j'aurais pu me voir. —
Enfin, mot, le dernier, et qui n'a pas de rime
Ici je suis dit tout ; consolez-moi bien.

LA RENAISSANCE DU *PETIT-SAINT-THOMAS*

Tout se fait à la vapeur à notre époque de progrès : le tour du monde en quatre-vingts jours, la mise en vente du *Petit-Saint-Thomas* en deux jours. Voilà qui ne ressemble guère à ces liquidations interminables qui semblent passer à l'état chronique et auxquelles, du reste, nos Parisiennes ne mordent plus.

C'était un véritable enlèvement que cette mise en vente. L'effet moral a été immense ; le résultat des plus rapides. Il n'est telle qu'une confiance séculaire pour entraîner le public. On avait fait dans cette salle devise : « Loyauté fait ma force », que le *Petit-Saint-Thomas* n'a cessé d'appliquer religieusement.

Toutes les marchandises de l'ancienne société, dont la jeune direction avait hâte de se défaire, n'ont fait que paraître et disparaître, comme dans une féerie. Ce mort imposant n'est chiffré par des sommes énormes ; mais on ne compte plus les millions par ce temps de gigantesques roulements de fonds.

Aujourd'hui, tout est fini. Le *Petit-Saint-Thomas* a fait maison neuve. Les quelques marchandises qui restent encore porteront une étiquette orange pour les faire reconnaître. A lundi la réouverture des magasins transformés. C'est aller vite en besogne.

La nouvelle gestion ne pouvait être inaugurée d'une façon plus brillante qu'avec sa magnifique exposition de printemps. Quelle ravissante métamorphose ! Tout semble imprégné de fraîcheur et de jeunesse, dans ces vastes galeries inondées de lumière !

Ces marchandises inédites ont toutes passé par l'examen scrupuleux d'un jury d'admission. Aucun article qui ne soit de premier choix. Les soieries, les lainages, la nouveauté, les lingeries, les batistes sont la propriété exclusive de la maison. Les robes et confections, toutes de grand style, rivalisent d'élégance avec celles des premiers couturiers en renom. Impossible d'imaginer des costumes enfants plus mignons et plus gracieux. Tout cela est riche, mais coquet, distingué.

Les ateliers fonctionnent avec une activité fébrile pour répondre instantanément à tous les caprices de la mode.

Le *Petit Saint-Thomas* met à votre disposition un magnifique album sur papier de luxe contenant 170 modèles nouveaux, dont les dessins originaux sont dus au crayon de nos premiers artistes parisiens.

ez, trouvera ainsi intéressamment exposées et l'on pourra en tirer jusqu'à 40 ou 45,000 exemplaires.

La presse d'imprimerie est, on le sait, une application du vieux principe de la vis. Mais, dans la presse typographique ordinaire, la fonction de la vis est très-limitée. Elle ne sert qu'à produire une pression énergique, mais qui ne peut être que momentanée. Il faut, en effet, que la vis, après avoir produit la pression, puisse être ramenée en arrière, pour que la feuille imprimée puisse être retirée et remplacée par une autre feuille blanche à imprimer.

Dans la presse autographique, au contraire, la vis est employée d'une manière continue. Elle ne sert pas à produire la pression, mais à la transmettre, de sorte que la pression est produite par un levier, qui agit sur l'autre de 1,000 francs, il pourrait faire un profit net de plus de 100,000 francs. Grâce à l'emploi de la plume autographique, un dessin, même très-compliqué, ou une écriture semblable à la typographie, peuvent être reproduits en autant d'exemplaires que l'on veut, sans avoir besoin de les copier à la plume. Il suffit, pour cela, de tirer sur papier mince, au-dessus du chiffre écrit à l'encre, la quantité d'épreuves désirée.

Cette application de la plume Edison ne sera pas du moins utile. — A.

La jeune, dernière et plus étonnante découverte de l'électricité, c'est l'électrographie, ou plume électrique d'Edison, qui reproduit instantanément, en toutes couleurs, des autographes, dessins, etc. Cette découverte est appelée à rendre de grands services à la typographie, à la lithographie, à la gravure, à la photographie, à la presse, à l'imprimerie, à la librairie, à l'enseignement, à la musique, à la géographie, à la cartographie, à la mécanique, à la physique, à la chimie, à la médecine, à la chirurgie, à l'art vétérinaire, à la pharmacie, à la botanique, à la minéralogie, à la géologie, à la paléontologie, à l'anthropologie, à l'ethnographie, à la zoologie, à l'histoire naturelle, à l'agriculture, à l'horticulture, à la viticulture, à l'industrie, au commerce, à la banque, à la bourse, à la navigation, à la marine, à la guerre, à la police, à la justice, à l'administration, à l'enseignement, à la science, à l'art, à la littérature, à la poésie, à la philosophie, à la théologie, à la politique, à la diplomatie, à l'histoire, à la statist

show us new colours, and the microphone will add show us new sounds. But just as the microscope renders not only visible, but large and conspicuous, what we could not previously discern simply because of its minuteness, so the microphone will render distinct and even loud what we could not previously discern, simply from the want of volume in the sound. The first result should be to provide those who are only deaf,—whose auditory nerve is not destroyed,—with a nearly perfect ear-trumpet,—not, of course, one which will enable them to gather in the general and confused sounds of a room with all the distinctness of good hearing, for the very essence of this instrument is that it can only magnify the isolated vibrations received on the vibrating-plate at the other end of the conducting-wire,—but still complete for the purposes of any isolated sound; that is, sufficient not only to make it audible, but to make it perfectly clear and distinct. But far more curious results should follow. With the help of the microphone, it should be possible to hear the sap rise in the tree; the hum of rushing against small obstacles to its rise, as a brook rushes against the stones in its path; to hear the bee suck its honey from the flower; to hear the rush of the blood through the smallest of the blood-vessels, and the increase of that rush due to the slightest inflammatory action. In fact, the new instrument should add a hundred times as much to the means of investigating the facts of both vegetable and animal physiology, as the stethoscope added to the knowledge of the structure of the heart and lungs; for while the stethoscope only collected the sound, the microphone will magnify it.

That, however, which strikes the imagination most in this wonderful discovery is not so much what it is sure to do, as the wonderful world of possibility it opens. It is almost certain that a ray of light strikes the surface on which it impinges with a definite force, and Mr. Crookes certainly supposed that he had found the means of approximating to a calculation of that force. But if this be so, there must be a definite sound caused by light touching a surface, and the new instrument may enable us not merely to see, but to *hear* light. It is quite conceivable that by the use of the microphone the chemist who is trying to analyse the spectrum of a star may be enabled to hear the first ray of the star strike upon his spectroscope, and to listen to the gentle rain of rays which follows while the spectroscope is exposed to that star, and then to exchange that gentle sound for that of the torrent which would follow when he exposed his instrument to the moon instead of the star. We may find that the rippling of the light from Sirius has a sound quite different in character from the rippling of the light from Arcturus or the Polar Star; and all of these music of starry light, if they can be heard at all, must make a sound as inferior to the cataract which rushes from the Sun, as the dash of a brook ... by temporary suffering still more savagely on the masters, treat them as enemies, and consider that the application of terror to them is, if not justifiable, at least pardonable. They are, moreover, at least as determined as of old. They know very well they cannot win. They see on every side men half-fed, and women asking charity, and children receiving it; they read, at all events, of incidents which seemed to Londoners as if taken from the Book of Chronicles; how the mob "came to Ell Hey worth's mill, but they burned not that mill, forsamuch as Ell had fed the people that day;" and they know their own leaders have no hope, yet believing their solution of the question to be the right one, they will not yield, but suffer everything, or break into sullen fury and destructiveness. Their children, —the big lads of eighteen—are not only not softened by education, but are foremost in the attacks on property and persons; while their women, hardly knowing how to keep their shawls from the pawnbrokers, wrap them round them for the last time to vote down peace. There is character in all this, and strong character, but it is not the temperate strength we all hoped to see produced by modern life. It looks as if education had only deepened the perception of suffering, without developing the readiness to avoid it by compromise, and had increased the perception of harshness, without increasing the perception of the claims of others. The men see less than ever that the master is a buyer of labour and the workman a seller, and that each is free to fix his own terms, subject to the right of his customer or dealer to reject them; while both sides are more ready, instead of less ready, to express irritation by violence. The readiness to resort to the rifle and the torch is most alarming, but not more alarming than the almost total absence, —we may say, after this ballot, the total absence—of any section of operatives who are upon the masters' side. Progress in the North, we fear, is not so rapid as had been hoped, at least if progress is to be defined as we should define it,—as an advance of large communities in sweetness, and light, and righteousness. We do not expect any more violence, because we think the workmen apprehend the terrible new power which the use of weapons of precision has placed in the hands of Governments, as against popular disorder—no mob, however brave or numerous, can stand for ten minutes against the breechloader—but we do apprehend that the division between masters and men, which seemed to be closing, has been reopened, and will be kept open for a generation. There is no Utopia visible in the result of that ballot.

The Sun.

TUESDAY, JUNE 11, 1878.

Mr. Disraeli should make haste to abandon the terrific name he has bestowed upon the latest invention. He calls it a telecosmopolene, and that won't do. A telescope is an instrument for seeing at a distance, and a telecosmopolene would be an instrument for seeing a vote at a distance. But as a vote cannot be seen, the name is inexpressive and absurd. By the way, these combinations of Greek words are perilous, unless the combiner possesses a thorough understanding of the Greek language.

Latest—News has reached us that the real name of the invention that was lately known as the telecosmopolene is the microphone.

THE DAILY EVENING TELEGRAPH—PHILADELPHIA, SATURDAY, JUNE 8, 1878.

THE MICROPHONE.

A WONDERFUL DISCOVERY INDEED.

An Instrument Which Does for the Sense of Hearing What the Microscope Does for the Sense of Sight—Experiments Successfully Made at the Mint Yesterday.

The discovery by Professor D. E. Hughes of Kentucky, better known in England than in America, that "sound can be recorded to the ear" excites considerable interest in the scientific world, and gives to humanity an instrument which does for the sense of hearing what the microscope does for the sense of sight. The first public test of the new discovery was made yesterday afternoon at the Mint, in the Assayer's private office in the Mint. The microphone was constructed of the following materials: A piece of hard wood, a piece of soft wood, a piece of lead, and a piece of the silicon of the Mint. Having delicately collected on the ends, a number of mercurial experiments were made, which, if successful, will, it is said, enable Professor Hughes to transmit the voice over a fine copper hair from any point there across a piece of smooth iron board, the notes produced in the transmission being clear and distinctly ringing the keys with each word that was spoken.

The faintest whisper was distinctly conveyed over the wire.

The tick of the new clever device, calling from the adjoining room, was heard by means of the instrument, through the closed doors, at a distance of several feet.

The microphone is of a duplex fly are quite audible in this apparatus.

The accompaniment of the instrument consists of a battery of two cells, and the weight of a single hair on the conducting wire produces a decided commotion on the receiver.

It is not a surprise to see one but an almost one that these wonderful effects are transmitted by a wire nearly as fine as a human hair, conducting the electricity from one room to another. But the fine wood machine makes the whole a most delicate.

Professor Stuches' Description of the Microphone.

Professor Hughes has published a paper recently on "The Action of Sonorous and Vibratory Varying Contacts of Feeble Electric Currents," which was communicated to the Royal Society of London by Professor Stuches, F.R.S., and read on the 24th of last January. The microphone is fully and clearly described in this paper, which is very interesting and fascinating. Speaking of the discovery, Professor Hughes of his discovery, Professor Hughes of his discovery, says: "The microphone, in connection with the telephone and phonograph, has become world-renowned, in a brief period in mental remembrance, and has been the means of bringing to the notice of the world a number of scientific facts which had made it known inventions and discoveries.

The microphone is the result of a series Professor Hughes has published recently on a feeble electric current, one made with a piece of hard wood, a piece of soft wood, a piece of lead, and a piece of silicon of the Mint. The instrument is so sensitive, he says, that the slightest whisper can be distinctly heard at a distance of several feet

Type A, Slide, as seen on N. O. R. and T. line, is the standard type for this machine. It is of exactly the same character as is employed in the Remington No. 2 and No. 7. The writing was simply done by the same method as was employed to obtain the specimen of writing on the Remington No. 2 and subsequent instruments. If it was a simple slanting or leaning of R, D, D, E, and P, it could produce exactly the same result. The writing is not quite so rapid, but as fast as I can write on the machine, and by the same we should have no effort; for if the effort is to be a question of the movement of R, D, D, E, P, it would seem to be impossible to write with the Remington machine as instantly the slant, shape, and character of A, upon S, side, could ever be, for instance, and no form of movement of the Remington can be as quick as to imitate the slanting character seen in the type there is slanting contact to a considerable degree, which could not be equaled by the Remington, and which could not equalize the influence of a slanting character.

Professor Hughes, in conclusion, says that he does not intend to take out a patent for his instrument, but to leave it to the free hands of discovery that invention. He believes that before long inventors will improve on the form and materials employed.

Possibilities of the Microphone.

Professor Hughes, in commenting upon the telephone, says: "Whether, in connection with the telephone, it can be applied to convey sounds to a distance without wires, I cannot say; but that it can be applied to intensify it, so as to make it even far more sensitive than it is, I have no doubt. I have, in fact, already obtained indications pointing in the same direction of distinct perception by conduction of movements which I could not hear by the ordinary means of hearing. I have not yet been able to carry my researches in this direction—but at least is known to be vastly increased by a similar application of a contact, such as the tapping of metallic wire on a bed or white paper, which I have described. I have, in fact, heard the tick of a watch at the distance of 40 feet. It is said that the march of a fly over the vibrating plate is audible. I have not myself been able to detect the sound, and I think the breathing of the fly is a sound almost like the unwinding of an elephant. *Just think what a sound-magnifying power would be!* I have obtained even a distance as the sound does at ordinary speech.

"It is not understood that it would be in any way impossible, for instance, to get a telephone which would convey articulate speech to a distance of 100 miles, or even more, from one end of the line and the number of a patient in Birmingham. The only difficulty is that the sound would be enormously attenuated, and each word undistinguishable when reproduced, but the range of the new instrument should be enormously extended, and the sound which the ear, or rather the brain, can hear and recognize as the voice of a friend. In London might be heard as a whisper. In the transmitting power of conducting the telephone and interrupting the current, I have found that the human voice can be heard at the distance of 100 miles, and indeed so much may be with the phonograph—the instrument which reproduces sounds. I have found that with the most convenient form of receiver, the whispering can be heard at the distance of 100 miles, and it is possible only to the ear of an electrician trained to hear."

"But the most curious results which we can at present contemplate are those which would accrue if we could find out how to fix the impressions of these sounds, either in specs of lime, as in the phonograph, or in some way in which we could preserve them, so as to be able to call up at our leisure, and the atmosphere will not show us new sounds, but, as it is, we have only to deal with the daily voices, barnyard and menagerie, and the sounds of the streets. Suppose, then, we could preserve the impressions of the voices of *dead and gone friends*, we could not only hear them speak, but we could make them sing. Fancy what a concert we should be able to provide those who are only deaf,—those auditory nerves which are paralyzed, but not destroyed, would respond to those natural sounds which we believe. With the help of the microphone, it should be possible to make the deaf hear, and the blind to read in reading Agassiz should constantly say:

"As to a book reading before the microphone, at least the two ways in which it could be done are obvious. One is the trend through the smallest imaginable wire of the impressions of the voice, as delivered over the phonograph cylinder, and the other is the transmission of the tests of both vowels and mutual physiology as the microscope has revealed it. Whether the microphone will be applied to help us write like stenographers only enhanced the result, the microphone will magnify it.

"But, however, which I have only imagination must fill out with a few words, I will say so much more in this article, as the wonderful world of possibilities is opened. It is not certain that a mere slight sound at the surface on which it impinges may not be magnified to the ear, and that the microphone may not be but little behind the means of communicating to a generation of their sons, that if this be so, there will be no more deafness, and that the blind will read

The Press.

MONDAY, JUNE 5, 1878.

PHONOGRAPHIC PHONETICS.

The phonograph has promised many a revolution in social and commercial affairs. When it is perfected and inwrought into our customs it may make many a change in our consciousness. Our writing it promises, which drivers of the quill will hail with satisfaction; and, perhaps, even the boys and girls at primary schools, and it may be even the whole race of philologists and phonetic savans. It is well known that alphabetic characters, both script and printed, are purely arbitrary. There are certain phonetic characters based on the Roman alphabet, and only less arbitrary in that they aim to represent all possible human articulations, as anatomy shall declare them, with precision and absence of confusion. Now, if the phonograph can produce all articulate sounds in imitations of tinfoil or any kind of medium, it can also transmit them to a recording instrument. It is only necessary to suggest the point. If a needle connected with the receiving disc records in depressions and quavers the sound vibrations of a speaker, it is only necessary to reverse the process in order to have them restored to sound. It can also be reproduced in mechanical signs on paper. Here we come to a true phonic alphabet. Like a the spectrum analysis, it may be only a system of lines within lines. That is of no consequence. It will be as easy to write on relief paper, with vertical and horizontal lines speeding over parallel lines, as by any other system. These varied lines, like those of the spectrum, will become the basis of a scientific alphabet exactly representing the physiological capabilities of the human voice. Here the phonetic problem is solved, and that for all languages on the face of the earth.

To this solution men of the midnight pen will look with immense interest. It is possible to speak a hundred and twenty words in a minute by a clear, rapid speaker. A quick pen will only transcribe about thirty words in the same time. If one could only speak his thoughts into a phonograph, and then by turning a crank grind them out into some kind of intelligible script, this would save three-fourths of the time of ordinary writing, and save a great deal of fatigue. All prof. minual men would be delivered from a tremendous bondage to the flesh if they could save their pens and their hands. To this improvement we look with especial interest, as both hastening the solution of many a philological problem and as lightening the work of the scribe editorial, legal or clerical. Hasten, Edison, in the perfection of thy little electrical magician!

The Sun.

MONDAY, JUNE 10, 1878.

The recent attempt of Prof. Hounzo, in London, to establish his claim as the discoverer of the microphone, has drawn from Mr. Edison the exposure of the Professor's pretensions which appeared in yesterday's Sun. Mr. Edison says that the so-called wonderful microphone, that transmits a sound as faint as the step of a fly, is nothing but a very defiant telephone; that the essential principle of the microphone was patented by him over six months ago in England, as that Prof. Hounzo might have discovered the microphone in the Patent Office! Mr. Edison also shows that Prof. Pierce, to whom Prof. Hounzo expressed his acknowledgments for aid, has long been in possession of a telephone, and in June or July last was shown all the wonders of the Menlo Park laboratory.

The Daily Graphic

TUESDAY, JUNE 11, 1878.

Edison has not invented anything since breakfast. The doctor has been called in.—*Boston Post.*

We shall have the great question regarding the inventor settled in time for dinner; for here we are Mr. Edison!—*Buffalo Express.*

America is still Ahead.

An English scientist has invented a contrivance to detonate that the sound made by a fly's foot in walking over the sounding board can be heard at the other end of the telephone, miles away. The English scientist, who is merely an imitator, will have to take a back seat, however. America's inventor, Mr. Edison, has perfected a machine by which you can hear a fly walk in London, by cable, the other side of the Atlantic, and, by utilizing the thousands of cables over, it will be a simple matter to have a fly walk from England to Australia.—*American Jewell, Paul's Nonsense Potter's Committee* could beat it and give you six.—*Philadelphia Bulletin.*

Edison is going to build little ph onographs for nursery toys.—*Buffalo Express.* This is an error. The speaking toys which will be for sale next fall will not be phonographs, or contain phonographic cylinders, but they will merely contain a little machine on which sound-waves will be transferred by metal on which sound-waves will be transferred by metal on which sound-waves will be transferred by metal

THE DAILY EVENING TELEGRAPH—PHILADELPHIA, SATURDAY, JUNE 8, 1878.

...ment removed at will, and is fitted to a circular, hollowed rubber frame work, which encircles a disk of tinfoil next to the central point in the diaphragm to which is fastened the needle that is the visible agent of recording speech. This needle is suspended from a light strip of steel, and is sensitive to the lightest touch, and the connections between the disk of tinfoil and this needle are made with wax. The tinfoil and needle do not touch the rubber or open space between the rubber mouth-piece and the tinfoil disk are also pieces of small pieces of rubber, which strengthen the vibrations of the needle and so assist in reproducing speech. Tinfoil is placed in the centre of the phonograph, the needle is accurately adjusted in position, so that its point shall traverse the spiral groove of the cylinder, and everything is ready for use. Prof. Dixon places his lips close to the mouth-piece, and says "Good evening Mr. Phonograph, these gentlemen have come to see the greatest wonder of the nineteenth century. Can you talk," turning the cylinder as he talks. Then he returns back the cylinder so that the needle point shall rest at the same place as before, the tinfoil where it did when he commenced, adjusted a long, tin tube, shaped somewhat like the mouth-piece, turned the crank, and his words were repeated distinctly and accurately. Exclamations of wonder, gratitude, surprise, and pleasure followed from those present. Then Prof. Dixon laughed long and heartily, and with marvelous facetiousness and histrionic talent mimicked the mouth-piece, and his words were repeated by the phonograph, exactly reproduced his mannerisms and tones. Then he spoke a couplet of Edison's doggerel, sayings into the mouth-piece, and the phonograph repeated them in tinkling tones, but not less distinct tones. "There was a little girl, she had a little curl, and it hung right over her forehead, and when she was bad, she was very, very bad, and when she was good, she was very good," and Rub-a-dub-dub, three men in a tub, etc. Tom Sawdrom was invited to make a speech and essayed, and the phonograph reproduced Sawdrom's peculiar tone and inflection in the style of—"Why don't you talk? why don't you talk? Give us a touch of Edison's best," dwelling on "best" in familiar and loud sort of way. Then was whistled "Yankee Doodle," but the phonograph whistled it better than Mr. Sawdrom did. Went it said to us personally, we fell in report. The phonograph sang "John Brown's Body," etc., and the phonograph sang it with a certain fervor and patriotic style. But the capacity of the sheet of tinfoil with its surface covered with indentations, was not exhausted yet, and a request was made the speaker, songs and tunes repeated of those who were watching its performance so intently. "Little girl," "Rub-a-dub," "Edison's best," "John Brown's Body," and strains of "Yankee Doodle," followed in sparkling confusion. But the professor's tinfoil gave out and he talked to us, giving the philosophy of the reproduction of the voice, much in the same form as he gave it on Thursday evening and as it was given in an article from the New York Independent, published in these columns a few week's since. And then we went home in the rain.

The phonograph again to-night.

THE MICROPHONE.

A WONDERFUL DISCOVERY INDEED.

An Instrument Which Runs for the Benefit of Hearing What the Microscope Does for the Sense of Sight—Experiments Successfully Made at the Stevens Yesterday.

The discovery by Professor D. E. Hughes of Kentucky, who has resided in Europe, of a new adaptation of the principle involved in Edison's instrument, the microphone, has excited the scientific community of the entire country, which has been constantly on the qui vive, since the first announcement was made, but which does not for the sense of hearing what the microscope does for that of sight. The new instrument is exactly what Professor Hughes claims for it, a microphone in the broadest sense of the word. It is not, as Mr. Edison, the inventor of the phonograph, has styled it, a telephone, but is a microphone in the truest sense of the word. It is simply a device to make audible to the ear the first ripple of the most delicate sound caused by the tread of a fly upon the surface on which it walks, or a particle of dust, a carbon dust, set 100 trembles distinctly enough to be heard by the ear. The instrument is very simple in construction, and can be put together by any one who has a little natural mechanical ingenuity and a few cents to spend for the necessary materials. It is not, however, to be supposed that the instrument is perfect, for it is not. It is quite capable of improvement, and will be improved, as the telephone and phonograph have been improved, by the ingenuity of scientific men, who will make a study of it. It is, however, in its present form a most wonderful instrument, and one which will have a most important effect upon the science of acoustics. It is better that before long it will be improved in the form and materials employed.

Possibilities of the Microphone.

The London correspondent, in commenting upon the performances of the microphone, wrote eloquently of the possibilities of the instrument, and predicted a thousand uses for it. Such is the case here.

The telegraphic letter from a distance without the aid of a telegraph wire, the microphone is capable of transmitting. Even the microphone is capable of transmitting. Even the microphone is capable of transmitting a message from Philadelphia to Washington, or to any other point on a line, by the interposition of a telegraph wire, but the microphone will not convey intelligence over the telegraph wire, but the sound is vastly increased by the interposition of a telegraph wire, and the microphone is useful as a delicate instrument for detecting and magnifying of sounds, as it is not of much use. It should be remembered that the microphone is not a telephone, and will not convey words or sentences as the latter is known, and that the mere breathing of the fly is heard by the microphone, and the sound of the fly's feet and also a conversation carried on in a normal tone is transmitted from a distance of a second close at hand.

We do not understand that it would be in any way impossible, for instance, to put a physician's stethoscope in connection with the microphone, and have the heart sounds of a patient heard audibly in the house and heart of a patient in Miss Nellie Grant's entourage had also been heard audibly in the house as a child in Richmond. With the extraordinary power of combining the telephone and microphone in one instrument, the possibilities are almost beyond conception. The form of the instrument is such that it is not of importance, provided the materials are of sufficient delicacy and sufficient to result in such vibrations as will be made. Carbon is used in preference to any other material, as its surface does not oxidize, and it is therefore more durable, and it is easily moved. The carbon is a conductor of electricity, but more delicate and costly in construction. I have also made very successful use entirely of

The Human Hair.

"The best form and materials for this instrument have not yet been fully settled upon," said Prof. Hughes to-day, "but I have made very successful use of the human hair in the microphone. If a pin, for instance, be laid upon or taken off a table, a sound would be emitted, or if a fly be walking upon a table, the sound of its feet would be heard. With a needle, or piece of wire, I touch the table, and with the tips of a watch, the tramp of a fly, and that to a person at a distance of a second close at hand, and the sound of either is quite distinct. Of course, we may fairly look for it to do far as, with regard to the sense of hearing, what the microscope does with regard to the sense of sight."

How the Results Are Due.

Professor Hughes then stated that an apparatus designed to show that the results are due to the primary principles by molecular action, and explained his time transmitter, which may be used in connection with the microphone or in it. The time transmitter is a clock-work arrangement, which, at 10, 20, 30, ninety seconds in the minute, gives a sound.

Professor Hughes then stated the results of an exterior experiment he has been trying, and the success of it so far as to encourage him to continue it. It was four separate pieces of wire, each one mile in length, and the ends of each were connected, and two terminals of a telephone. Then, and two terminals of a microphone. Then, and

...ment was detected in one case, and mentioned as distinctly with the line and distinctly with the four [illegible].

Then it is made to open on 10, 0, 0, 0, and 0, until the carbon is placed in the electrical current is about one-third that of the original current. The sound is heard by an attendant in a distant room, and is distinctly heard by a person close at hand. If the result was simply to be transmitted to a distance, it would be a very popular contrivance. Without them it would be a most unpleasant instrument. If 10, 0, 0, 0, 0, simply the number of the carbon is used, and not 10, 0, 0, 0, 0, it would be less as a test also if the carbon 10, 0, 0, 0, 0, would be less as a test also if the carbon is placed in the electrical current. It would have an effect, but the effect is not to be a source or entanglement of 10, 0, 0, 0, 0, 0, 0, 0, 0, 0, it would be a source of entanglement. It

A telephoning extract from Mr. Prescott's book appeared in the *Journal of the Telegraph*, April 16, 1877, will show that the diminishing of the distinctness in the new transmitter with Mr. Edison has introduced, the vibrating diaphragm is done away with altogether, it having been found that the carbon button alone is sufficient to vibrate the tongue of the transmitter in its place. With the old vibrating diaphragm the articulation produced in the receiver was found to be due to the sound waves impinged with the vibrating disk sometimes in advance of the voice, which probably results from the latter overpowering in the receiver the sound waves set in motion by the transmitter. In the new instrument, now here exhibited, the sound is more clear and unmistakably heard that a whisper can be distinctly heard in unconnected and unformed. The inductive plate, which consists of a thin piece of mica covered with a conducting lamp black, and connects a considerable portion of the sources waves upon the small carbon button or button, and thus produces a greater effect in an electric current. The part of the receiver is to apply sufficient heat on the disk then could be obtained to heat on the disk then could be obtained if only the small resistance of the battery.

The chemistry of the carbon telephone can be used as a measure of minute degrees of heat; it will move proportionate than the preceding. This is a fact of which I am sure. Mr. Edison has informed me in Washington. Mr. of the law of April last. A copy of that paper was sent by me to Mr. Preece, the consulting and electrician to the British Post Office, and I have positive evidence that he received this before the presentation of the so-called "microphone" to the Royal Society, and before the address of that man as an invention of Mr. Edison.

Mr. D. E. Hughes, electrician to the London Post Office Department, was in this country a few years ago, and I have been informed by a secretary, I feel assured that the statement was true, making, including the principle of the carbon telephone and the microphone, that Mr. Hughes was in this country between under pretense, I may say, to be making the presentation of this telephone, and subsequently of the microphone, but that he was in fact here to steal, by sketches, publications and by pictures in general, my electric appurtenant, as he always manifested a great desire to be aware of promotion my discoveries to the British people.

I am informed by the solicitor of Mr. Preece in this matter as to merely a violation of my rights as an inventor, but as a gross infringement of the copyright of my book, entitled "Electricity Simplified," New York, very truly,

Menlo Park, N. J., June 6, 1878. THOMAS A. EDISON.

"ZANOBIA."

Improvement in Dynamo-Electric Machines.

It is stated by the *Bldg. Pol. Jour.* that the firm of Schuckert, in Nurnberg, have lately been devoting attention to the improvement of dynamo-electric machines, for galvano-plastic purposes and the electric light. Their machines are like the Gramme, but the following points may be noted. The rotating iron ring, wound with copper wire, is a flat disc; thus the wires of the two long sides of the cross section come under the action of the flat-shaped magnetic poles, and the induced currents of the two sides combine having the same direction. The whole wire length is thus utilized. Centrifugal force at high velocity does no injury. Again, the iron ring is not in one massive piece, but in several ring discs, separated from each other by ecanite, pasteboard, or the like, the whole ring being held together by brass rivets. The object here is to hasten the disappearance of remanent magnetism, in rapid change of the poles, and to obtain the maximum of magnetization. This construction allows of the firing of the ring or metal without disturbing inductive action, since only very small part of the wire is in contact with it, and the evil effects of a possible heating are obviated.

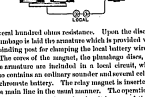
EDISON'S PRINCIPLE DELAY.

Mr. Edison has recently invented an ingenious and novel relay instrument, based upon an entirely new principle. He takes advantage of the property which a plumbago possess of decreasing its resistance enormously under slight pressure. Thin discs of that material are placed upon the crapped poles of an electro-magnet, (see diagram), the coils of which have



several hundred ohms resistance. Upon the discs of plumbago is laid the armature which is provided with a binding post for clamping the local battery wire.

The coves of the magnet, the plumbago discs, and the armature are included in a local circuit, which also contains an ordinary sounder and several cells of bichromate battery. The relay magnet is inserted in the main line in the usual manner. The operation is as follows: When the main circuit is opened the attraction for the armature ceases, and the only pressure upon the plumbago discs is due to the weight of the armature itself. With this pressure only the resistance of the plumbago to the passage of the local current amounts to several hundred ohms; with this resistance in the local circuit the sounder remains open. If now the main circuit be closed, a powerful attraction is set up between the poles of the relay magnet and its armature, causing a great increase in the pressure upon the plumbago discs, and reducing its resistance from several hundred to several ohms, consequently the sounder closes. So far the result differs but little from the ordinary relay and sounder. But the great difference between this relay and those in common use, and its value, rests upon the fact that it repeats or translates from one circuit into another, the relative strengths on the first circuit. For instance, if a weak current circulates upon the line in which the relay magnet is inserted, the attraction for its armature will be small, the pressure upon the plumbago discs will be light, consequently a weak current will circulate within the second circuit; and on the contrary, if the current in the first circuit be strong, the pressure upon the plumbago discs will be increased, and in proportion will the current in the second circuit be increased. No adjustment is ever required. It is probably the only device yet invented which will allow of the translation of signals of *variable strengths*, from one circuit into another, by the use of batteries in the ordinary manner. This apparatus was designed by Mr. Edison for repeating acoustical vibrations of variable strength in his speaking telegraph, a description of which we shall shortly publish.

Telegraphy and Mr. Prescott's Book About It.

The wonder of the telephone, which at present engages the popular mind, will serve also to direct attention to the vast progress of the import- 4 science of which it is but a new and problematical development. Practically electricity itself, the mysterious foundation of modern telegraphy, has hardly owned the first conditions of a science until within the last years, and electric telegraphy, as every one knows, has existed but a little more than a generation, and its great applications and triumphs have been made and won within the memory of every person of middle age.

What the steps of this progress have been, and their order, would take a volume to indicate; but when we consider that the first business line was put in operation in 1838, in Bavaria, and the first in this country six years later, we realize the rapid advance and immense extent of the system of communication which now covers the whole globe. It would be hardly instructive to print here the number of miles of wire in use, or the force of men employed in their constructing or working; nor is it needed to enlarge the myriad indispensable services the telegraph is constantly performing for the business, the information and interest, and the comfort and affection of mankind, for these are familiar to all. And if one would gain an adequate conception of the scale and continual activity of mind employed in the utilization and improvement of the great invention, we should refer the inquirer to Prescott's "History and the Electric Telegraph," the latest work of Mr. George B. Prescott, and the most thorough treatise on the subject, whether considered practically or theoretically, that has been issued in this country at least.

Mr. Prescott, who was one of our near neighbors a few days ago, is well-known as the accomplished electrician of the Western Union Telegraph Company, and, probably, the American most fit to do this particular work. And yet he has hardly made just what the public want; for while, in every detail, the book is enormous itself, there is no continuous and comprehensive grasp of the subject into one narrative, such as might have been given separately without injuring the value of the treatise as a manual for electricians and for those studying the advance made in telegraphy both as a science and as an art. In this matter he has it in his power to supply what some of the explanative offer—a lucid history of the telegraph all over the world.

Our present electric telegraph would be more properly described as electro-magnetic, for it depends upon the magnet—whose kindred to electricity, though so certain, is not at all understood—as much as upon the electric battery; chemical action and magnetic induction being the two component forces of telegraphy. Mr. Prescott's careful and perspicuous descriptions of the batteries, machines and the multitudinous combinations and suggestions of inventors, for the first time afford the American reader a complete acquaintance with what European scientists have been doing in this field. Of a great number of these we presume we may say few telegraphers know anything.

* * *

In short, if Mr. Prescott's book possessed the addition we have suggested, of a chapter of continuous summary and broad account of all the reach of telegraphy and the various modes and incidents of its working, it would be as entirely satisfactory to us, the laity, as it now to the narrower circle of students and scientists who are specially concerned with its subject.—*Springfield Republican.*

The Telegraph.

Exhibition of Bell's Telephone.

Prof. A. G. Bell gave three lectures and exhibitions of the operation of his Telephone or speaking telegraph, at Chickering Hall, in this city, on the 17th, 18th and 19th May. Owing to the high prices charged for admission and defective business management, the attendance was small. The exhibitions of the operations of the Telephone were moderately successful, though not so much so as has been reported at previous exhibitions in Boston and Providence.

Telegraphic Phenomena.

LAFAYETTE, INDIANA, May 16.

To the Editor of the Journal of the Telegraph.

Some time ago I constructed a telephone after a new pattern of my own invention, and connected it to the main line, and sang different tunes here. They were distinctly heard at Otis 82 miles north of this city. Others along the line heard the tunes the same as if it came from an organ. I then tried words, they went all right but could not be understood. Has any telephone ever been made that by *the use of a battery* words could be understood at the distant end of the line? When the test was made in Canada on the new "Dominion" lines, and words were spoken, was the main battery disconnected? I do not believe the human voice has ever been sent over a line where a make and break circuit vibrator was used. Will you please enlighten me as well as others of this "mystery?"

GEO. B. HAYES.

Prof. Bell's speaking telegraph or telephone is worked either with a battery current or a permanent magnet. It is understood that for vocal purposes the permanent magnet is preferable, but it is practicable to use the battery current, and it has been done very frequently. We are not informed as to the conditions under which the test was made on the Dominion lines in Canada.

ELECTRIC PEN AND DUPLICATING PRESS.

SIMPLE IN OPERATION,
PERFECT IN WORK,
UNRIVALLED IN SPEED.

FROM 1,000 TO 5,000 COPIES CAN BE MADE BY THIS PROCESS FROM A SINGLE WRITTEN STENCIL.

It is the cheapest method of producing Circulars, Price Lists, Market Quotations, Pamphlets, Catalogues, Lawyers' Briefs, Contracts, Abstracts, Legal Documents, Manifolds, Time Tables, Freight Tariffs, Labels, Letter and Bill Heads, Maps, Architectural and Mechanical Drawings, Bills of Fare, Music, Insurance Policies, Press Reports, Bankers' Forms, etc.

3,000 of these instruments are in use among Railroad and Telegraph Companies and prominent Business Firms.

Send for samples of work and description.

NEW TELEPHONIC INVENTIONS.—Mr. Joseph P. Noyes, of Binghamton, N. Y., writes to the *Tribune*, describing a new device for increasing telephonic sounds. He introduces into the electric current a V-shaped apparatus, consisting of two strips of somewhat flexible material, joined or in electrical connection at their lower ends and slightly parted at the upper. The material is a conductor of very high resistance. To each upper end a wire of the circuit is attached. It will be seen that, if the V is gradually closed, the current will pass over less and less of the poor conductor. This is facilitated by rounding the inside edges of the strips along the line where the contact is to take place. Mr. Noyes then applies a diaphragm so that its movements of vibration (by sound waves) shall open and close the V. By this device, it is stated, far louder sounds are obtained than with the ordinary telephone. At Philadelphia, Professors Edwin J. Houston and Elihu Thomson, of the Central High School, have for some months past been endeavouring to effect a relay of telephonic messages from one circuit to another. Professor Hughes's construction of the microphone has now enabled them to solve this problem, as that contrivance can be made to repeat on a new circuit the most delicate vibrations that have started from a Bell telephone. The new relaying apparatus has been shown at the Franklin Institute, and was executed there satisfactorily.

THE MICROPHONE IN THE PULPIT.—The *Halifax Guardian* says that a young gentleman, well known in connection with a firm of telegraph engineers in the town, has contrived to have his sermons at home. He placed a microphone in the pulpit of a chapel in this town, and connected it, by means of a private telegraph line, with a house over a mile distant. Every part of the service was distinctly heard by the owner of the house, with the exception of a few words rendered indistinct by the preacher becoming a little excited, and shaking the microphone, the presence of which he never dreamt of, or he might have been somewhat nervous at the idea that his sermon was being conveyed away he knew not whither. So faithfully did the microphone do its work that the chapel-keeper was heard to close the doors after service, walk up the aisle, and up the pulpit steps, in conversation with some one. During the week experiments have been made in the schoolroom of another chapel, and the singing of the scholars was transmitted and retransmitted over a number of telegraph lines with remarkable clearness. The idea is about to be put to practical use, the gentleman already referred to having given instructions that his house should be connected with that of a gentlemen near, in order that an invalid may hear the service from one of the churches in the town.

DISPUTED INVENTION OF THE MICROPHONE.

We are glad to have the opportunity of printing the following communication :—

TO THE EDITOR OF THE ELECTRICIAN.

SIR : With reference to your article headed "Disputed Invention of the Microphone," I enclose you two messages sent to New York, which I hope you will publish.—YOURS, &c.,

June 25, 1878. W. H. PREECE.

To NORTH GREEN, NEW YORK.

Please give following message to Associated Presses and to Ashley :—

"Pray give the most absolute and unqualified denial to the statements made by Edison respecting me. Hughes has not brought out any thermopile. His microphone is quite a different instrument to Edison's telephone. It was worked at first without any communication with me, or information imparted by me, in any way whatever. I knew nothing of it until it was shown to me, together with Professor Hughes and Mr. Norman Lockyer. I am in no way whatever a coadjutor of Hughes. "W. H. PREECE."

"I emphatically endorse every word of the above message "D. E. HUGHES."

CORRESPONDENCE.

THE MICROPHONE AND THE TELEPHONE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR : Allow me to make a few observations on the Microphone and Telephone, and the remarks thereon in the articles by Messrs. W. Smith and Sankrock in numbers two and three of your journal.

From a rough description of the Microphone, in a late number of the *Débats*, I constructed one, adapting an ordinary cigar box and the carbon from a used Leclanché. The vertical rod was a piece of ordinary hard lead-pencil. All the phenomena described in *The Electrician* could be easily obtainable on a hundred miles wire in length between my cabin house and the town, and on which all my previous telephonic experiments had been made.

The battery power used varied from one to twenty Meneitti's, which rendered indistinct by the preacher becoming a little excited, and shaking the microphone, the presence of which he never dreamt of, or he might have been somewhat nervous at the idea that his sermon was being conveyed away he knew not whither. So faithfully did the microphone do its work that the chapel-keeper was heard to close the doors after service, walk up the aisle, and up the pulpit steps, in conversation with some one. During the week experiments have been made in the schoolroom of another chapel, and the singing of the scholars was transmitted and retransmitted over a number of telegraph lines with remarkable clearness. The idea is about to be put to practical use, the gentleman already referred to having given instructions that his house should be connected with that of a gentlemen near, in order that an invalid may hear the service from one of the churches in the town.

The battery power used varied from one to twenty Meneitti's, with high internal resistance, and one to ten Leclanchés, with very low resistance. I find the lower the battery power the better are the results, and with one Leclanché everything goes most successfully over the distance mentioned. The insertion of extra resistance in the circuit makes but a comparatively trifling difference in the results ; my watch was clearly heard on the circuit with an interpolar resistance of 15,000 ohms, using four Leclanchés.

In the last paragraph of Mr. W. Smith's article I observe that he anticipates being able to converse through our longest cables ; whilst I find that resistance enters little or nothing into the question, a stumbling-block has yet to be overcome in the cable's electrostatic induction. Together with my colleague at Otranto, Mr. Eggington, we have had repeated trials both ways on this cable, 187 knots in length. No variation whatever in the battery power enables us to hear even mechanical sounds, the rapid current-waves from the microphone's vibrations being unable to sufficiently quickly discharge themselves through the telephone ; in fact, the line remains attracted the whole time the microphone is in circuit, and, by making and breaking "earth" contact at the receiving end, the sound appears the same, but stronger, than that from a Morse armature on short circuit*.

Our latest trials were with a positive current on the microphone, and a weaker negative one at the receiving end, but still without success, and certainly, unless we can devise a double-current microphone, cables are cut off from its field of operations. With Corfu, 150 miles, no better results are obtainable, and, for the present, all further trials have been suspended.

Mr. Sankrock very justly takes exception to the term "microphone." It does not do for sound what the microscope does for sight. To my idea it should be termed a "sound finder," seeing that sounds absolutely inaudible to the sharpest human ear become with it quite distinct ; for instance, a hair drawn across the surface of the microphone can never be heard by the naked ear, yet through the microphone the noise of its passage is unmistakeable. Audible sounds are not magnified ; a pistol fired over a microphone does not cause you to hear a salvo of artillery, nor does the ticking of a watch increase to the noise of a steam-engine.—Yours truly,

W. G. FORSTER.

Zante (Greece), June 10th, 1878.

* The telephone coil has not more than 25 ohms' resistance. Bearing in mind this principle, nearly any single goodly sounder can respond to the slightest electro-magnetic instrument's coils.

A MOST DELICATE THERMOSCOPE.

Thomas A. Edison, of New York, is inclined to dispute certain discoveries recently made in England. We were among the first to publish an account of the delicate "thermopile" (a better term, which we here adopt, is the electrical thermoscope"), which forms part of the discoveries of Professor D. E. Hughes. Professor Hughes's discovery was in this case the result of an accident. He had been making certain experiments with glass tubes, and for the moment, not having a glass tube at hand, he took up a quill, and fashioned it for his purpose. The result he expected to see was not obtained ; in fact, the experiment failed, but the failure drew attention to some other important facts. The quill contained carbon, and under the action of heat the quill expanded more than the carbon. The differential action resulted in the increase of the ohmic resistance, and so influenced the current as to set in motion the galvanometer. We are now informed that Mr. Edison long since constructed an instrument for measuring to a astonishing exactness the smallest variations of temperature. In his experimental researches he discovered that, under certain electrical conditions, carbon was exceedingly sensitive. The slightest change of temperature affects the expansive and contractile properties of certain bodies, we might almost say all bodies, but some to a greater degree than others, and by resting on the carbon such a better or a worse contact to be made in the electric circuit, according as the temperature is raised or lowered. Not only is Edison's instrument sensitive to changes of temperature, but it also indicates the increase or decrease of moisture in the atmosphere. Mr. Edison, indeed, goes so far as to say that "spitting on the face will be indicated by a movement of the galvanometer needle." Surely, the drawing rooms of our transatlantic friends ought to be furnished with one of these instruments in a new case, with a recording apparatus, so that the number of expectorations in the room might be daily registered. We do not like the record of our sins to glare upon us too strongly, and are apt to say "out of sight out of mind ;" but a gentle reminder of this sort might prove effective in reducing expectoration to a minimum.

This wonderful instrument, however, is a very simple affair, after all. Everybody can make one. The most important parts of the apparatus are the battery and the galvanometer. In the electrical circuit we connect the galvanometer and some carbon buttons. The carbon is in contact with the wire-conductor of the circuit, or between the metal plates. The current passes through one plate, then through the carbon, and through the other plate to the opposite pole of the battery. Mr. Edison connects the plates by a piece of hard-rubber or gelatine, but it will at once be seen that the best material to connect the plates is a non-conductor which is exceedingly sensitive to heat or moisture. The instrument proper then requires carbon contacts, such that the expansion or contraction of a second substance under the influence of heat or moisture alters the contact to make it more or worse contact, and thus provides for or increased current by or worse resistance at the points of contact, or, on the contrary, decreased resistance and decreases the current. Mr. Edison's instrument is given as follows by the *New York Herald*:—" Mr. discovery is given as follows by the *New York Herald*:—" Mr. discovery is given as follows by the *New York Herald*:—" Mr. Edison next exhibited his new discovery, the thermopile, to measure infinitesimal degrees of heat. Mr. Edison explained the instrument to the *Herald* reporter in the following words :—" It consists of a carbon button placed between two metallic plates. A current of electricity is passed through one plate, then through the carbon and through the other plate. A piece of hard-rubber or of gelatine is so supported as to press against these plates. The whole is then placed in connection with a galvanometer and an electric battery. Heat causes the strip of hard-rubber to expand and press the plates closer together on the carbon, allows more current to pass through, and deflects the needle of the gal-

accordance with the vibrations of the disc, producing thereby a corresponding variation in the electrical resistance of the carbon cake, which is placed in circuit with a battery and receiver and which are connected respectively with the two plates of platinum.

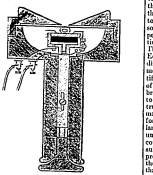

FIG. 1.

The essential principle of Mr. Edison's transmitter consists in causing a diaphragm, vibrating under the influence of sonorous vibrations, to vary the pressure upon and therefore the resistance of a piece of carbon which is placed in the circuit of a voltaic current, to which is impressed, by the variations of its resistance, no undulatory motors which is capable of reproducing in a telephone at a distant station sonorous vibrations corresponding to those at the transmitting end of the line.

Mr. Edison's instrument is acoustically similar to Professor Bell's telephone, and bears a resemblance electrically to a special form of the microphone of Professor Hughes, but it is just the similarity to the one which constitutes its difference from the other. It resembles the Bell telephone in taking up sonorous vibrations by means of a diaphragm placed in front of a resultajcon, and it differs from it in the method by which it converts the vibrations of the diaphragm into waves of electrical force. It resembles Professor Hughes's microphone in the employment of a battery current in the circuit of which is interposed a resistance which is variable, but it differs from the microphone in the means by which that variation of resistance is brought about by the sonorous vibrations imparted to the instrument. It may be said to occupy a place between the two, and it would be difficult to say which it most resembles, or from which it differs most widely.

It has for many years been well known to electricians that the resistance of all conducting bodies, and we may assume of all substances, varies under variations of pressure, and this fact has been noted in the construction of relays and certain other telegraphic instruments where good contacts are required, it being the aim of the manufacturer in such cases to insure as small a resistance as possible at the contact points by the employment, wherever practicable, of strong springs for increasing the pressure between them.

Some imperfect conductors exhibit this property in a more marked degree than others, and the fact that the resistance of powdered carbon varies in a remarkable degree under variations of pressure, was taken advantage of by M. Clerac, of the Administration des Télégraphes in Paris, as far back as the year 1865, who constructed at that time resistance tubes containing powdered carbon, the resistance of which could be regulated by increasing or diminishing the pressure upon the contents of the tubes by means of an adjusting screw. This property of carbon has also been made use of by Mr. Edison in his carbon telephone, and in the year 1873 he constructed tubes similar to those of M. Clerac as rheostats for artificial cables, but we understand that Mr. Edison discovered the property independently of M. Clerac, and without a knowledge of what had previously been done by that electrician. A new and important application, however, which has been described, Mr. Edison substituted a carbon cake for the section of India-rubber tube between two of its material, could not be relied upon for keeping the instrument in adjustment; and, in order to get rid of an unpleasant metallic ringing tone emitted by the spring, shorter and stronger springs were tried, and Mr. Edison was led by the greatly improved result to do away with the spring altogether, to insert a solid substance between the carbon and the diaphragm, and to make the diaphragm as thick that its vibration under the influence of the loudest tones became inappreciable. With an instrument so constructed, Mr. Edison states that he obtained perfect articulation, and that whispered conversation was clearly transmitted to a distant station. There can be no doubt that at this point Mr. Edison was sailing round and very near to the discovery of Professor Hughes, and it furnishes one more instance in the history of scientific research of an experimenter being on the verge of making a great discovery, but missing it by broaching off in another direction, or by failing to see in the phenomena under observation their true explanation. Thus the independent discovery made by Mr. Edison was that carbon in various forms, and more especially in the form of compressed lampblack or soot, is variable in electrical resistance under variations of mechanical pressure. The discovery of Professor Hughes is, that all conducting substances may be employed with equal success, provided that their surfaces are not unalterable under the influence of an electric current, or if unalterable that their oxides are dispersed as rapidly as they are formed. The experiments of Professor Hughes demonstrate very clearly that sonorous vibrations throw into molecular activity or tremor all substances within their range of influence, and that if words or notes be sounded in the neighbourhood of a bundle of wires, it will take up the vibrations constituting the sounds, and if on its surface be placed a steel point, or there be two or more electrically connecting surfaces in contact with one another, the slightest molecular agitation of the resistance board is communicated to the conducting material, and no undulatory character is imparted to, or otherwise unvarying current passing through it, corresponding in its undulations to those of the sonorous vibrations by which the original tremor was produced. It will thus be seen that Mr. Edison's discovery is but a special case of the larger and more comprehensive discovery of Professor Hughes and just as the theoretical discoveries of the two inventors differ, so do the constructions of their respective instruments, and the reasons given for those differences differ also. Mr. Edison uses carbon because he finds that it makes a poor electrical contact under feeble pressure, which contact increases as that pressure is increased, while Professor Hughes employs carbon in certain forms of his microphone on account of its property of making the best electrical contact with very slight pressure indeed. For the same reasons Mr. Edison finds it necessary to insert a diaphragm in all forms of his apparatus, that being the mechanical contrivance employed by which sonorous vibrations are converted into vicissitudes of mechanical pressure, and by which variations in the conductivity of the carbon or other material is insured. It is true he has made his diaphragms in some cases as much as $\frac{1}{2}$, in. in thickness so as to reduce to a minimum their amplitude of vibration, but the experiments of Professor Bell, as well as the researches of Lord Rayleigh, have shown that metallic diaphragms are capable of vibrating under the influence of sound through amplitudes so minute as to be inappreciable and under sonorous vibrations so small as to be altogether unsuspected before. On the other hand, Professor Hughes employs no diaphragm at all, the sonorous vibrations in his apparatus acting directly upon the conducting material or through whatever solid substance to which they may be attached.

In considering Mr. Edison's most interesting instrument it is important to point out the very essential differences which exist between it and the microphone of Professor Hughes, because the name *carbon* telephone might otherwise lead to the idea that on account of carbon being employed in some forms of the latter instrument there is greater similarity between them than really exists.

For long circuits the arrangement adopted by Mr. Edison is shown in the diagram, Fig. 2, in which A is an induction coil in which the secondary wire s is within and enclosed by the primary wire p; the former has a resistance of from 150 to 200 ohms. The coil c is to the length of or resistance of the line. The receiving telephone R is very similar in principle to Professor Bell's instrument, but differs from it in the fact that the thin iron diaphragm is polarised by being attached at a point on its edge to one pole of the magnet which is bent twice at right angles to suit the construction; the other pole carries a coil of wire, the resistance of which is about 75 ohms, which is placed below and concentric with the diaphragm as in Professor Bell's instrument. P K is a polarised relay which closes a circuit, in which is a local battery E and call bell B, when a signal

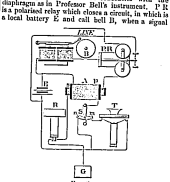

FIG. 2.

from the distant station is sent through the line. At S is a switch, the lever of which either (1) by being placed at a disconnects the transmitting telephone T and battery E from the induction coil A; (2) by being placed at b cuts out the battery E to the line through the induction coil; or (3) by being placed at c throws the transmitting telephone T with the induction coil and line. By the first the apparatus is ready to receive a call signal from the distant station, by the second it is connected for transmitting a signal, and by the third the telephonic circuit between the two stations is closed and articulate communications may be sent.

For lines of shorter circuits, that is to say, from 1 to 30 miles, Mr. Edison prefers the arrangement shown in Fig. 3, which differs from that illustrated

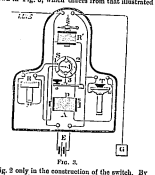

FIG. 3.

in Fig. 2 only in the construction of the switch. By inserting a plug in the upper hole, by which the pieces 1, 2, and 4 are connected, the telephone circuit is completed, but when the plug is placed in the lower hole, thereby connecting 4 and 3, the apparatus is connected for receiving and transmitting call signals, the sounder or bell B, the battery E, and the transmitting key being thereby brought into circuit.

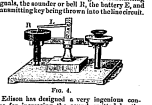

FIG. 4.

Mr. Edison has designed a very ingenious contrivance for increasing the sound emitted by the vibration of the diaphragm of a telephone by which

FRENCH TELEPHONIC EXHIBITION.

Attention, it has been necessary to give to readers a telephonic exhibition. Mr. Edison contains this exercise by Mr. Lassimone.

ENGINEERING.

FRIDAY, JUNE 21, 1878.

EDISON'S CARBON TELEPHONE.

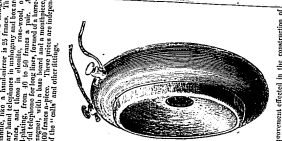
Attention has been directed to the invention of Professor Hughes noticed in a recent number of ENGINEERING, and to the instrument which were then described in this journal, but since then Mr. Edison has brought out a modification of his telephone, which differs from the original instrument in a manner which is of considerable importance, and which we have therefore thought it desirable to describe. The original instrument, as described by Mr. Edison, was constructed as follows:—A thin diaphragm of sheet iron, about 2 in. in diameter, was placed in front of the pole of a magnet, and at a distance from it of about $\frac{1}{100}$ in. The pole was surrounded by a coil of fine wire, and the whole was fixed in the ordinary manner in the mouthpiece of a telephone. The diaphragm was connected by a wire with a button of hard carbon, which was pressed against a second button of carbon by a spring. The second button was connected with the terminal of the coil, and the circuit was completed through the line wire, the receiving telephone, and the battery. The carbon buttons were mounted in a small cup of vulcanite, and the spring was adjusted by means of a screw. The vibrations of the diaphragm caused a variation in the pressure between the buttons, and consequently in the resistance of the circuit, and thus produced undulatory currents which reproduced sounds like the original ones. Although articulate talking resulted in the transmission of words, it was found that the instrument was not sufficiently sensitive for the purposes of ordinary conversation. Mr. Edison has therefore modified it in the following manner:—The carbon button has been replaced by a cup filled with carbon granules, and the diaphragm is connected with a platinum plate which presses upon the granules. The cup is mounted on a stout spring, and the pressure of the granules upon the diaphragm is adjusted by means of a screw. The vibrations of the diaphragm cause variations in the pressure of the granules upon the platinum plate, and consequently in the resistance of the circuit, and articulate talking resulted in the transmission of words. The instrument is, however, still imperfect, and Mr. Edison is now engaged in endeavouring to overcome the difficulties which still exist. He has found that the sensitiveness of the instrument is greatly increased by the employment of a local battery, and that the articulation is much improved by shunting the receiving telephone with a resistance of about 150 ohms. Mr. Edison has also found that the articulation is greatly improved by shunting the transmitting telephone with a resistance of about 30 ohms. The best results are obtained when the resistance of the shunt is equal to that of the telephone. The shunts are used in the following manner:—The receiving telephone is placed in a shunt of 150 ohms, and the transmitting telephone in a shunt of 30 ohms. The shunts are then placed in the circuit, and the instrument is ready for use. Mr. Edison has also found that the articulation is greatly improved by the employment of a condenser in circuit with the telephones. The condenser is composed of sheets of tinfoil separated by sheets of paper, and has a capacity of about 2 microfarads. It is placed in circuit with the telephones, as are also previously mentioned shunts. With the instrument as modified by the above arrangements, Mr. Edison has succeeded in transmitting articulate talking over a circuit of 1,000 miles of ordinary telegraph wire. Mr. Edison has also found that the articulation is greatly improved by the employment of a microphone transmitter in connection with the telephone. The microphone transmitter used by Mr. Edison is that invented by Professor Hughes, and described in ENGINEERING, vol. xxv., page 417. Mr. Edison has found that the articulation is greatly improved by the employment of a microphone transmitter in connection with the telephone. The microphone transmitter used by Mr. Edison is that invented by Professor Hughes, and described in ENGINEERING, vol. xxv., page 417. Mr. Edison has found that the articulation is greatly improved by the employment of a microphone transmitter in connection with the telephone. The microphone transmitter used by Mr. Edison is that invented by Professor Hughes, and described in ENGINEERING, vol. xxv., page 417.

* See ENGINEERING, vol. xxv., page 417.

FRENCH PERAMBULATIONS AT THE PARIS EXHIBITION.

The collection of locomotives from the French railways presents an interesting feature at the Exhibition. I am not sure that the "whole" form of half the engines does not belong to the "ugly" class of half the engines. Be that as it may, it is hard to find anything more ugly than the locomotive, unless it be the tender. Both, however, have their uses, and I suppose we must not look for beauty in anywhere like a watch. In running long lines of railway, the question of coal is a very important one, and in the north the great parts of the journey are performed by coal, which is carried round from the tender, instead of being supplied from the side of the line, as in England. The tenders are therefore very large, from 40 to 50 French a yard. The engines are also large, and the cylinders are outside. The central compound engine was noticed. It is a "Mallet" engine, and is known in France as of the "Mallet" system. It consists of a pair of high-pressure cylinders, and another pair of low-pressure cylinders, placed under the smoke-box, and driving on the second pair of wheels. The high-pressure cylinders are 15 inches in diameter, and the low-pressure cylinders 30 inches, and the stroke of the piston is 24 inches. The steam is used expansively in the high-pressure cylinders, and then passes into the low-pressure cylinders, where it is used expansively. The engine is said to work well, and to consume little coal. The boiler is of the ordinary type, and has a working pressure of 10 kilos. per square centimetre. Coal decreases the pressure, May [illegible] pressure upon the [illegible]

M. Nicolas has also exhibited a locomotive, which is fitted with Edison's tramway, and the telephone improvements in connection therewith. The engine is fitted with the telephone, so that a man in front can hear what is going on behind. The telephone is partly fastened to the roof of the cab, and partly fastened to the front of the tender, so as to be partly protected from the weather. The line between these two points is a distance of 20 yards, with a battery of four cells between them.



An improvement effected in the construction of Edison's "Motograph" has been introduced into America. *Mr. Kennedy* points out that Edison was the first to suggest the use of a vibrating armature in connection with the electro-magnet of the telephone. The difficulties of the articulation of the human voice are due to the inertia of the diaphragm with respect to the pole or the magnet—a pressure, while having sufficient force for it to move, is unable to move it with sufficient rapidity. It is found, however, that different degrees of pressure may be exerted upon the diaphragm at more than one point, and hence the idea arose of using a vibrating armature, which, by its own inertia, would be less liable to follow the vibrations of the diaphragm, and thus to produce a more perfect articulation. In certain cases, however, as in the Edison "Motograph," the inertia of the armature is used to the advantage of the instrument, as it is thereby rendered capable of receiving impressions from a greater number of vibrations than would otherwise be the case. The addition of the vibrating armature to the "Motograph" has, it is stated, increased its articulating power to a very great extent.

* See Discussion, page 499 ante.

STEAM ENGINES AT THE PARIS EXHIBITION.—No. I.

No one can complain that there is any deficiency, so far as quantity goes, in the show of steam engines at Paris. We have succeeded in counting altogether 285, not including the semi-pumping engines and several others exhibited, chiefly for the sake of driving some special machines rather than as separate exhibits, such as the large engine in the Pierlot industries or another in the Austrian bakery. Including all these the number is very closely 300, if it does not exceed it. Of the 285 engines, 53 are exhibited along with their boilers, mostly as "semi-portables" of some form (in some cases, however, of a size quite precluding the notion of portability), and of these 52 are vertical engines (including 39 French and 17 British), and the remainder horizontal (23 of them

[There was unfortunately a misunderstanding on the part of the [illegible] of the drawings of the Paris Exhibition, which were to be published in this number, and they will appear in the next issue. We regret the delay, which has been unavoidable.]

it is capable of calling attention. This telephonic call, which is represented in Fig. 1, consists of a simple stand I, in which the receiving telephone R is suspended in a vertical position, having its mouth pierced with holes, and directed upwards. Upon the centre of its diaphragm rests, when the instrument is not in use for speaking purposes, the end of a light free lever L, pivoted to the central pillar of the stand, and the excessive blows against this lever when the diaphragm is in vibration, and the consequent rebounding of the lever from the vibrating surface, produce a sound which may be heard at some little distance from the instrument, and must necessarily be much louder than the sound emitted by the telephone without the aid of the lever. The principle of its action is very similar to that of the well-known acoustical experiment of suspending around a glass bell a number of pellets, which by being thrown away by the vibrations of the bell render those vibrations apparent to the eye, and cause them to become louder to the ear.

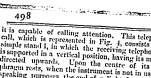


FIG. 5.

Fig. 5 is another arrangement experimented with by Mr. Edison for calling attention in telephonic circuits. At each end of the line, and in circuit with it, is placed an electro-magnet, represented in the figure by M and M′, and in front of the poles of each is fixed a magnetised steel tuning-fork A and B. When one of these forks is set into vibration by mechanical or electrical means, a vibratory electric current is induced in the coils of the magnet opposite the vibrating fork, which current, traversing the coils at the distance station, sets into sympathetic vibration the tuning-fork at the other end, whose period of vibration being precisely equal to that at the transmitting station, receives the successive attentions impulses exactly synchronously with its own period, and the consequence is that its amplitude of vibration increases until its further progress stretches against a bell, there being one at each station, represented by C and D, and gives a call signal. A somewhat similar arrangement is shown in Fig. 6,

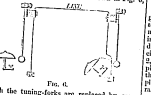

FIG. 6.

in which the tuning-forks are replaced by magnetised pendulums of equal length, opposite which are placed electro-magnets in circuit with the line. Upon causing one of the pendulums to swing in the presence of its electro-magnet or magneto-inductor a vibratory current is transmitted through the line, and the pendulum at the distant station is set swinging by impulse synchronous with its own period of vibration, and a bell is struck when its amplitude has sufficiently increased. Both in this and in the previous arrangement provision is made for stopping the bell out of the way at the transmitting station, while a call signal is being sent.

Fig. 7 represents an idea which has been suggested by Mr. Edison for constructing a telephone in which electrostatic currents are employed instead of voltaic or magneto-electric. In this curious arrangement an electrophorus is placed at each end of the line represented in the figure by B and C. Over each electrophorus is placed a metallic disc, plug-ended, and mouthpiece E or A, which in its vibration approaches and recedes from the highly-charged electrophorus below, and in so doing is supposed to induce an electrical disturbance at the distant station, and to produce sounds and articulate speech. This idea beats upon the face of it a paper stamp, and we venture to say that it never arrived at greater maturity than being sketched upon paper. Another equally visionary telephone is shown in Fig. 8, in which A and B represent two of De Luc's dry piles, having their opposite poles joined by the line wire. Each pile is supposed to contain some 20,000 discs, and the vibration of the diaphragm at either end is intended to cause an electrical disturbance in the discs in its immediate neighbourhood, transmitting an undulatory current through the line, and reproducing, by a process which Mr. Edison does not explain, articulate speech at the distant station. Mr. Edison has also been conducting experiments with a view of constructing a diaphragm of vulcanite. In this arrangement delicate thermo-pile placed in front of a leg instrument at the further end. Mr. Edison states that he has found that the temperature of such a diaphragm is, during its vibration, much lower in its forward motion than in its return, and upon this principle he hopes to construct a telephone to be worked by those variations of temperature producing corresponding variations in a thermo-electric current, and traversing a receiving instrument at the distant station.

FIG. 7.

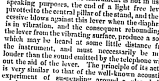

FIG. 8.

FIG. 9.

Fig. 9 represents an interesting and very ingenious experimental telephone, which was constructed by Mr. Edison in the course of his experiments prior to the production of his carbon instrument; in this apparatus the vibrations of the diaphragm were caused to throw into or cut out of circuit one or more of a series of resistance coils, 1, 2, 3, 4, &c., arranged in a circle below the diaphragm, the number of coils in the circuit, and therefore its total resistance varying with the amplitude of vibration of the diaphragm. In this arrangement, as in the carbon telephone, an induction coil C is employed, the transmitting and receiving instrument being in circuit with the secondary wire and battery, and the secondary coil being connected to the line and to earth. Mr. Edison states that with this instrument articulate utterances were transmitted, but the results were harsh and disagreeable. This result could have been anticipated, as the variation of resistance in the circuit must make a sudden change on passing each coil in drawn into or cut out of the circuit, and all the delicate variations consisting between each are lost when their corresponding variations of electrical current in between that produced by throwing in and that produced by cutting out one of the resistance coils—or, to express it by a graphical illustration, the variations of the voice would be represented by a gradually rising or falling curve or wave, while the electrical resistance of the circuit in the telephone figured in Fig. 9, and therefore the strength of current, could only be represented by a series of steps.

The last to which we shall refer of Mr. Edison's experimental telephones is represented in Fig. 10. In this arrangement, to which Mr. Edison has given the name water telephone, the variation of resistance is obtained by attaching to the diaphragm of the transmitting telephone a wire bent in the shape of the letter U, the ends of which, as the diaphragm vibrates, being plunged more or less deeply into two cells of water which are connected thereby, a variation of resistance is produced and an undulatory current is transmitted to a receiving telephone at the other end of the line.

We believe the first suggestion of the employment of water for this purpose is due to Mr. Varley, of Dublin, who by placing a drop of water between the contacts in a Reis's transmitter was enabled to obtain an undulatory current, and thereby to transmit through a telegraph wire certain articulate sounds.

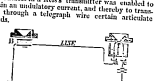

FIG. 10.

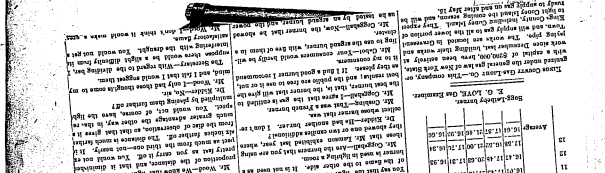
In all the telephonic instruments which have been described in this notice, the importance of using a diaphragm for causing sonorous vibrations to produce variations of electrical resistance is pronounced in every instrument described by Mr. Edison and Professor Hughes, however, has through his great discovery been enabled to show that variations of resistance can be imparted to an electrical current not only without a diaphragm, but with very much better results where no such accessory is employed, for in the conversion of the physical forces the one into the other, there must always be some loss at each change; and those physical processes which involve the fewest conversions must of necessity be accompanied with the least aggregate loss. The microphone of Professor Hughes may be looked upon as an acoustical relay by which sonorous vibrations are enabled to throw into a telephonic circuit an undulatory current from a powerful constant source, and thereby produce a great augmentation of the minute sounds which actuate the sensitive relay, and the result is that otherwise inaudible sounds are magnified into loud tones. This is its great difference from a result from all other systems, which receive a strong voice at the transmitting end, giving it out at the receiving end in far feebler tones. This difference may be illustrated by looking through a telescope with the eye at one end or the other. In the microphone, sounds are enlarged as objects are by a telescope used in the usual way, while to all other telephones they are diminished as objects are when seen through a telescope with the eye against the object glass.

Some time ago we published a description of a new form of [illegible] invented by Mr. Edison, and which he called the "Motograph." We have since received from Mr. Edison a letter, in which he states that the instrument described by us was not the latest form of the "Motograph," and that the improvements effected in it were not described in our notice. We regret that this should be the case, but we were unaware that any improvements had been made in the instrument, and could only describe it as we found it. We have since received from Mr. Edison a letter, and, in consequence, recall from our readers the "Motograph" described in our last issue.

WALLACE'S DUPLEX MAGNETO MACHINE



LE MONDE DE LA SCIENCE ET DE L'INDUSTRIE 14 JUILLET 1878

l'appareil servant dans les opérations chirurgicales et dans toutes les circonstances qui requièrent cette qualité particulière de l'éponge, de s'imbiber facilement et d'absorber les liquides. Soutenue et constamment superchargée en eau, aussi ne saurait-elle trouver d'équivalent, bien moins encore être surpassée pour les soins qu'exige la propreté, du l'emploie beaucoup dans le commerce pour l'emballage d'objets fragiles ; verre, cristaux, etc. Elle est dans ce cas bien préférable au coton, à la paille, aux copeaux. Les matelas et les coussins d'éponge ne sont ni rares, ni nouveaux. Les différents emplois de ce produit maritime sont si variés qu'on ne saurait les énumérer tous, aussi peut-on aisément prévoir que le commerce des éponges est encore à son début, que, dans quelques années, il sera mis au rang des branches importantes, et que de grands capitaux, des flottes entières, et des milliers d'hommes seront employés à la récolte d'un objet de commerce dont on trouve chaque jour une nouvelle application.

Dans le courant de l'année 1877, 250,000 livres d'éponges, représentant 625,000 fr. environ, furent exportées de Bahama. De ce nombre 100,000 livres furent importées aux États-Unis et le reste dans le Canada et en Angleterre. La récolte augmentera encore cette année.

Les variétés d'éponges connues dans le commerce sont nombreuses ; leur finesse et leur qualité déterminent leur valeur. Les pêcheries emploient environ 500 vaisseaux qui stationnent habituellement dans les eaux des différentes îles, et 2000 hommes, la plupart de couleur. Les meilleures éponges sont celles d'Alcove. La durée d'une pêche varie de deux à six semaines et dépend de la grandeur du navire et de l'état du temps ; les plongeurs ne pouvant travailler dans une eau crue.

A sa sortie de l'eau, l'éponge est noire et forme une masse gélatineuse exhalant une odeur fétide, qui s'accroît avec la putréfaction de la masse. Dès que la quantité d'éponges recueillie a été jugée suffisante, on les amène au rivage ; là on les fait exposer au soleil où elles sont entièrement dans le sable pendant plusieurs jours. Quand la décomposition est achevée, on frappe ces masses noirâtres avec d'énormes maillets ; les corps des polypes s'en détachent alors et tombent en poussière. A cette opération succède le lavage à l'eau de mer, puis les éponges sont chargées à bord.

Anciennement on se servait d'un procédé tout différent. Après avoir retiré les éponges du sable où on les avait préalablement enterrées, on les exposait dans une cage de fer, à l'action des vagues, qui les purifiaient de tous les corps étrangers, mais le sel de mer qui corrodait les éponges fit bientôt abandonner ce moyen.

Arrivées à destination, les éponges sont triées suivant leur qualité et le produit de la vente est partagé, après déduction faite des frais d'approvisionnement, entre les plongeurs et les armateurs. Une dernière préparation consiste à émonder l'éponge, c'est-à-dire à enlever toutes les parties dures et pierreuses, après quoi elles sont vendues, à la livre, aux commerçants qui les expédient dans tous les pays du monde.

L'AVENIR DU PHONOGRAPHE PRÉDIT PAR EDISON

Tout ce qu'on a déjà dit du phonographe n'est rien en comparaison de ce que nous promet M. Edison dans le dernier numéro de la *North American Review*. Le célèbre inventeur va appeler, dans un avenir rapproché, des perfectionnements considérables à son merveilleux instrument.

De fait, il suffit d'un peu d'attention pour se convaincre que les applications du phonographe sont illimitées et qu'elles créeront une véritable révolution dans les relations humaines. Comme il est possible que le phonographe, avec ses perfectionnements, combine à la suppression, dans une certaine mesure, de l'écriture et de l'imprimerie, on pourrait croire cependant, à première vue, que vouloir chercher de telles applications à cet instrument, c'est, pour ainsi dire, faire un pas en arrière.

Qu'on s'étonne aujourd'hui de la solidification des gaz ? Le phonographe nous permet de solidifier quelque chose de bien plus subtil : la parole et la pensée humaine. Au lieu des boîtes à musique et des orgues de Barbarie, dont les sons plus ou moins harmonieux écorchent nos oreilles, on aura maintenant le phonographe, qui reproduira fidèlement les chefs-d'œuvre des grands artistes vivants, les charmantes mélodies écloses par la Patti, Deux cents qui soupirent l'un pour l'autre pourront se dire à travers les monts et les mers ce qu'ils sentent, ce qu'ils craignent, ce qu'ils espèrent. Le phonographe reproduira exactement à l'oreille de l'un les accents de l'autre. M. Edison s'occupe actuellement à perfectionner l'instrument dans ses détails mécaniques. « La principale utilité du phonographe, écrit-il, consiste en ce qu'il permet d'écrire les lettres à la dictée. C'est vers ce perfectionnement que tendent ses efforts. Voici comment est construit son dernier appareil imaginé pour ce but.

Sous le stylet est disposé un disque de cire portant sur l'une de ses faces des rainures en spirale ; ce disque est mis en mouvement par un mécanisme d'horlogerie ; les rainures sont si rapprochées que l'on peut imprimer environ 40,000 mots sur une seule feuille d'étain de 30 centimètres carrés.

Une feuille d'étain est placée dans le phonographe, le mécanisme d'horlogerie mis en mouvement, et la dictée faite comme à l'ordinaire dans l'embouchure d'un cornet acoustique. La feuille est ensuite enlevée, placée dans une enveloppe *ad hoc*, et expédiée par les moyens ordinaires à son correspondant. Celui-ci, plaçant cette feuille dans son phonographe, met en mouvement le mécanisme d'horlogerie et prête l'oreille. Il entend alors la voix et les paroles qui ont été dites dans l'instrument.

On peut conserver les feuilles et reproduire leur contenu à volonté. Rien de plus aisé que de graver deux feuilles à la fois en les superposant ; on peut ainsi conserver un double de sa lettre phonographique plus facilement que des lettres ordinaires. Inutile de faire ressortir la rapidité avec laquelle ces dictées peuvent se faire. La personne qui suit la reproduction de la lettre peut entendre 150 à 200 mots par minute, tout en vaquant à d'autres occupations. Ajouter à cela le ton, l'accent, l'expression, l'émotion même avec lesquels ces missives sont transmises, et vous aurez une idée des merveilleux résultats de cet appareil.

Les avantages de cette invention sur les moyens de correspondance dont nous disposons actuellement n'échapperont à personne. Il faut espérer qu'on ne tardera pas à en faire l'expérience sur une grande échelle.

Qui sait si l'usage des lettres ne disparaîtra pas un jour ; si, au lieu de lecteurs, il n'y aura plus que des auditeurs ? Serait-il permis de supposer que la connaissance de la lecture et de l'écriture devînt superflue ?

Ainsi que le dit avec raison M. Edison, en écoutant son-

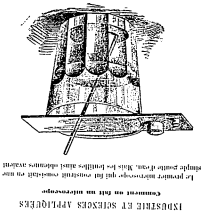
vue des divers objets que nous venons de décrire, on peut se faire une idée de la richesse et de l'importance de cette partie de l'Exposition. Elle est vraiment digne de fixer l'attention des savants et des hommes d'étude, et elle ne le cède en rien aux autres parties de l'Exposition pour ce qui est de l'intérêt qu'elle offre à la curiosité générale.

Après avoir examiné le photocalque perfectionné et l'héliographie, nous nous sommes arrêté devant un appareil très-simple et très-ingénieux, destiné à donner des épreuves positives de dessins au trait, sans avoir recours à l'emploi de la chambre noire. Cet appareil, qui est dû à M. Poitevin, est connu sous le nom de *Copiste*. Il se compose d'une planche de bois, sur laquelle on place le dessin à reproduire, et d'une glace qui vient s'appuyer sur le dessin. Cette glace est recouverte d'une couche de gélatine bichromatée, qu'on a préalablement exposée à la lumière, et qui a été ensuite lavée à l'eau froide. Cette couche, qui est devenue insoluble dans les parties qui ont été frappées par la lumière, est restée soluble dans les autres parties. Pour obtenir une épreuve, on expose le dessin à la lumière, et on le laisse pendant quelques minutes. Puis on lave la glace à l'eau froide, et on la fait sécher. Le dessin apparaît alors en traits blancs sur un fond jaune. Il ne reste plus qu'à le reporter sur du papier ordinaire, ce qui se fait très-facilement par un simple frottement.

Nous avons vu fonctionner cet appareil, et nous avons pu nous convaincre de la facilité avec laquelle il donne des épreuves très-satisfaisantes.

Nous signalerons encore, dans la classe de la photographie, les appareils de M. Lerebours, qui sont très-remarquables, et qui ont été récompensés par le jury international. Nous citerons également les appareils de M. Dubosq, qui sont très-ingénieusement disposés pour la projection des images photographiques, et qui ont été employés avec succès par M. Duboscq, dans ses cours de physique.

Nous ne pouvons pas entrer dans de plus longs détails sur cette intéressante partie de l'Exposition, et nous nous bornerons à dire que les photographies exposées par MM. Bayard, Bingham, Blanquart-Evrard, Bisson frères, Cuvelier, Delamarche, Disdéri, Fortier, Gaudin, Gustave Le Gray, Mestral, Nègre, Robert, Salmon, Thiesson, Vallou de Villeneuve, Victor Regnault, etc., etc., sont remarquables à tous les points de vue, et qu'elles ne le cèdent en rien à celles qui ont été exposées par les photographes anglais.



MICROSCOPE A LENTILLE DOUBLE. 1

Fonctionnant dans l'obscurité, ce microscope est destiné à éclairer par réflexion les objets opaques.

MICROSCOPE A LENTILLE DOUBLE.

Construction and Use of the Microscope.

L'INSTRUCTION ET LES SCIENCES APPLIQUÉES.

Nous avons vu, dans les quelques lignes qui précèdent, que le microscope est un instrument destiné à faire connaître à l'homme les infiniment petits, c'est-à-dire les objets qui échappent à son regard, à cause de leur petitesse. Nous allons maintenant donner quelques détails sur la construction et sur l'usage de cet instrument.

Le microscope le plus simple est celui qui est représenté dans la figure 1. Nous le mettrons sous les yeux de nos lecteurs, afin de leur faire mieux comprendre ce que nous allons dire.

Cet appareil simple se place sur un pied support en bois, ou en métal, et il se compose d'une petite lentille de verre, ou d'une petite boule de verre, qui est fixée dans un petit cadre de métal. Cette lentille est placée au bout d'une tige de métal, qui peut monter ou descendre à volonté, et qui est munie d'une vis de rappel, afin de pouvoir donner à la lentille la distance convenable pour que l'objet soit bien au point. Enfin, la tige de métal est fixée à une tige horizontale, qui peut tourner autour d'une autre tige verticale, et qui est elle-même fixée au pied du microscope. Cette dernière tige est munie d'un petit miroir, qui peut prendre toutes les positions nécessaires pour recevoir la lumière du jour, ou celle d'une lampe, et la renvoyer sur l'objet à observer.

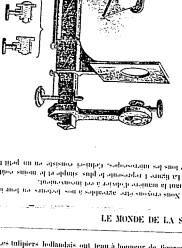
Pour se servir de cet instrument, on place l'objet à observer sur la petite table, et on le dispose de manière à ce qu'il soit bien éclairé par le miroir. On met ensuite l'œil à peu de distance de la lentille, et on regarde l'objet à travers cette lentille. Si l'on a bien disposé le miroir, et si l'on a donné à la lentille la distance convenable, on aperçoit l'objet très-grossi, et on peut alors l'examiner à son aise.

Le microscope que nous venons de décrire est le plus simple de tous ceux qui ont été construits, et il ne donne que des résultats très-peu satisfaisants. Aussi ne l'emploie-t-on que dans les cas où l'on n'a besoin que d'un grossissement très-faible, comme, par exemple, pour examiner les petites bêtes qui vivent dans l'eau, ou pour observer la structure intime de certains tissus végétaux ou animaux.

Pour obtenir un grossissement plus considérable, on emploie un microscope composé, qui est représenté dans la figure 2. Nous allons donner quelques détails sur la construction de cet instrument, afin de faire bien comprendre à nos lecteurs la manière dont il fonctionne.

Le microscope composé se compose d'un pied support en bois ou en métal, d'une tige verticale, qui peut monter ou descendre à volonté, et qui est munie d'une vis de rappel, d'une tige horizontale, qui peut tourner autour de la tige verticale, et qui est munie d'un miroir, d'une petite table, et d'un tube de métal, qui est fixé à l'extrémité de la tige horizontale. Ce tube est formé de deux parties, qui peuvent glisser l'une dans l'autre, et qui sont munies chacune d'une lentille. La lentille qui est placée à l'extrémité inférieure du tube est appelée *objectif*, et celle qui est placée à l'extrémité supérieure est appelée *oculaire*.

Pour se servir de cet instrument, on place l'objet à observer sur la petite table, et on le dispose de manière à ce qu'il soit bien éclairé par le miroir. On met ensuite l'œil à peu de distance de la lentille oculaire, et on regarde l'objet à travers cette lentille. Si l'on a bien disposé le miroir, et si l'on a donné à la lentille oculaire la distance convenable, on aperçoit l'objet très-grossi, et on peut alors l'examiner à son aise.



MICROSCOPE A LENTILLE DOUBLE. 2

Les tulipiers hollandais ont tenu à honneur de figurer à l'exposition, en offrant aux amateurs l'occasion de contempler leurs plus riches collections de tulipes.

On peut voir en avant du palais du Trocadéro, à droite, une vaste corbeille de 12 mètres de diamètre, dans laquelle ils ont planté 10,000 tulipes qui toutes, aujourd'hui, sont d'une belle venue et qui commencent à s'ouvrir de fleurs.

Cette corbeille, qui sera d'un effet ravissant lorsque toutes les plantes aux mille nuances qu'elle contient seront fleuries, fait partie de l'exposition florale de la Hollande. Elle ne sera certes pas un des moindres attraits des jardins du Trocadéro.

L'AME DES PLANTES

Le sommeil des plantes

III

Les plantes des champs et des jardins fournissent, comme les plantes d'eau, des faits dignes de frapper l'attention de l'observateur et l'esprit du penseur.

Les plantes se marient ; le moment du mariage est annoncé par l'apparition des fleurs. Il y a des fleurs qui, comme la primevère, le fuchsia, la mauve, etc., renferment des anthères et des étamines que d'autres plantes possèdent également, et dont le concours est nécessaire pour que les plantes donnent des fruits et des graines. Tandis que dans les fleurs que nous venons de citer, la fécondation a lieu par des causes que nous pourrions appeler accidentelles, d'autres possèdent, hors de l'époque de leur nuptiale, des mouvements volontaires. La vératrine, une herbe assez commune qui croît au fond des eaux tranquilles, se passe du bon office du vent ou des insectes, entremetteurs ordinaires. Les fleurs pistillées s'épanouissent, à l'extrémité, des pédoncules qui peuvent s'allonger assez pour les amener à la surface de l'eau ; elles ne s'épanouissent que lorsqu'elles sont arrivées dans cette patrie. Les fleurs staminées ou mâles, sont groupées au fond de l'eau sur de courts pédoncules qui ne peuvent s'allonger. Lorsque le moment de l'union est arrivé, le groupe de fleurs mâles se détache brusquement du pied qui le porte, monte à la surface de l'eau et s'approche successivement à l'aide des mouvements de l'onde, de chaque fleur pistillée. L'acte accompli, le long pédoncule remonte au fond de l'eau la fleur femelle qui mûrit son fruit.

Le phragmome est plus curieux encore dans la Rue (*Ruta graveolens*). Les dix étamines de la fleur s'épanouissent l'antière ; déjà on distingue au centre de la fleur ; lorsque l'époque de la fécondation est arrivée, chacune approche du pistil à son tour, selon son numéro d'ordre. Par ces contacts répétés, la fécondation n'en est que mieux assurée.

Enfin, voyons le *Cyclamen*.

Lorsque les semences sont mûres, la tige de la fleur se tord en spirale, jusqu'à ce qu'elle touche le sol et, pénétrant de force dans la terre, elle y loge les semences. Celles-ci reçoivent la nourriture de la racine-mère, car, transportées ailleurs, elles périssent.

Nous pourrions multiplier les exemples, mais nous croyons en avoir assez dit pour que l'on ne puisse nier l'intelligence des plantes. On prétend que les animaux sont doués d'une vie supérieure à celle des végétaux ; nous croyons, au contraire, que celle des plantes est au moins égale.

EDISONIANA

La carrière d'un homme célèbre. — Un nouveau thermomètre ; Le microtasimètre Edison. — Un duel phonographique. — Le téléphone à poupe de charbon. — Edison, inventeur du microphone.

Thomas Elva Edison est le nom d'un homme qui, par ses talents et ses découvertes, semble personnifier le génie de l'invention.

Né à Milan dans l'Erié, Ohio (États-Unis d'Amérique, le 11 Février 1847, il dut subvenir lui-même à son existence, dès l'âge de huit ans. Il demanda d'abord son pain aux modiques bénéfices qu'il trouvait dans la vente des journaux ; mais par l'essor de son tempérament nerveux, par la sagacité de son intelligence et la fermeté de sa volonté, il ne tarda pas à se distinguer au milieu de ses compagnons. A douze ans, il s'était déjà assuré le monopole de la vente des journaux sur toute la ligne de Detroit, dans cette nouvelle sphère, son article favorite et ses talents trouvèrent un vaste champ de travail. Il prit à son service d'autres jeunes gens et fonda un journal, le *Grand Trunk Herald*. Il l'imprimait dans un atelier ambulant, établi dans un fourgon. Il en était à la fois le rédacteur et l'imprimeur. Tous les employés de la ligne lui fournissaient des articles. Son rapide d'abonnés compta bientôt plus de 400 noms. Pour répandre plus facilement son journal, M. Edison s'arrangea avec les chefs de diverses stations, pour qu'ils empruntassent sur de grands tableaux noirs les titres des articles de fond de son journal qu'il leur adressait par le télégraphe ; cela augmenta beaucoup la vente de son *Herald*. Tout jeune encore, il se procurait ainsi les moyens de parvenir à sa future carrière. L'emploi fréquent du télégraphe l'initia bien vite à tous les phénomènes et à toutes les lois connues qui concernent l'électricité, et, à 12 ans, il abandonnait le journalisme pour établir un atelier de physique, en vue surtout de se vouer à des recherches sur les perfectionnements à apporter aux divers systèmes télégraphiques en usage. Là, il eut occasion de déployer tous ses talents.

Il passa ensuite quelque temps au service du télégraphe des chemins de fer, puis il entra dans une administration privée.

A un âge, nous le trouvons à Cincinnati, cherchant à établir l'idée, en germe encore, de son télégraphe duplex, et, quelques années plus tard, M. Edison était considéré comme l'un des plus habiles et des plus savants physiciens des États-Unis. Le nombre des brevets qu'il prit pour des inventions est incroyable ; on en compte plus de deux cents. En dernier lieu nous le voyons s'établir à Menlow Park, New-Jersey, travaillant dans de vastes ateliers, et disposant de fonds considérables qui lui permettent de réaliser ses idées.

Aujourd'hui, le monde entier connaît le nom à jamais illustre de M. Edison.

***

Edison, l'inventeur du phonographe, vient de découvrir

1. Poche terminale de l'étamine contenant le *pollen*.

un nouvel appareil appelé le micrato-mètre, qui sert à mesurer la pression infinitésimale.

Cette invention laisse bien derrière elle la pile thermo-électrique, destinée à indiquer les plus faibles changements de température, et le radiomètre, qui indique la puissance motrice des forces les plus subtiles.

Le professeur Edison a eu projet une foule d'applications de son nouvel appareil, parmi lesquelles des thermomètres et hygromètres d'une sensibilité inconnue jusqu'ici. L'inventeur croit pouvoir parvenir à mesurer la chaleur des étoiles les plus éloignées et à peser les rayons du soleil.

***

Le phonographe s'est distingué dernièrement par la perfection avec laquelle il a réussi à reproduire des *soli* de cornet à piston, exécutés par le célèbre Levy, à New-York. Cet artiste possède la remarquable habileté de faire rendre à son instrument des sons qui « n'ont pas », c'est-à-dire qu'il peut jouer des airs une octave plus bas que tous les autres cornettistes. Le phonographe sorti à son honneur de la lutte qu'il soutint contre son redoutable adversaire, aux applaudissements des sympathiques auditeurs qui avaient tenu à fêter la présence de M. Edison à New-York.

***

En même temps que l'on signalait dans l'ancien monde la découverte du microphone, M. Edison faisait paraître dans les journaux scientifiques américains une notice sur un nouveau téléphone qu'il avait imaginé, il y a quelque temps déjà. Depuis plusieurs années, M. Edison était occupé à des recherches sur les propriétés remarquables que possède le charbon préparé d'une certaine manière. Il est parvenu à produire un téléphone *sans membrane vibrante* ; il lui a substitué un simple disque de charbon de corne.

***

M. Edison vient d'adresser au *Scientific American* une réclamation de priorité sur l'invention du microphone dont la découverte lui appartient, dit-il.

M. Edison déclare que le principe du microphone de Hughes n'est pas seulement identique à celui de son téléphone à charbon, mais encore que les plus petits détails sont empruntés à ce dernier instrument. La subdivision du charbon a fait l'objet de nombreuses expériences lors de ses recherches sur son nouveau téléphone, et quant à la métallisation du charbon, il la pratique depuis nombre d'années.

Le passage le plus intéressant de la lettre de M. Edison, est celui où il attribue à M. W. H. Preece, collaborateur du professeur Hughes, à Londres, le plagiat scientifique du microphone. M. Edison avait nommé M. Preece son représentant en Europe pour ses inventions, et lui communiquait par lettres privées ou bulletins scientifiques, ses recherches et les résultats de ses travaux. Il paraît qu'en avril dernier, Edison lui avait adressé des notes sur ses recherches sur l'emploi du charbon pour mesurer un infime degré de chaleur ; or, on sait que c'est ce qui forme l'un des caractères spéciaux du microphone. C'est ensuite de ces communications, dit M. Edison, que ses idées et ses inventions furent mises à profit par MM. Preece et Hughes, et que ceux-ci réinventèrent le microphone. En terminant sa lettre, M. Edison déclare qu'il considère la conduite de M. Preece en cette circonstance, « non-seulement comme une violation de son droit d'inventeur, mais comme un véritable abus de la confiance qui M. Preece avait su s'attirer sous des dehors d'amitié. »

Nous sommes curieux d'apprendre ce que répondront MM. Hughes et Preece à ces graves accusations de M. Edison.

UN NOUVEL ÉLECTRO-AIMANT

Un nouveau genre d'électro-aimant a été décrit récemment dans l'*English Mechanic* ; sa force doit être considérablement plus grande, à dimensions égales, que celle des électro-aimants en fer à cheval. L'invention en est due à M. Joule.

UN NOUVEL ELECTRO-AIMANT FIG. 1

quoiqu'on lui ait donné quelquefois le nom d'aimant Jamin. Voici comment on peut fabriquer soi-même à peu de frais et facilement un aimant Joule.

Prenez un bout de tuyau à gaz ordinaire, de la longueur de 10 centimètres environ et d'un diamètre de 3 centimètres,

UN NOUVEL ELECTRO-AIMANT FIG. 2

et limez-le de manière à lui donner une base plate, fig. 1 ; l'ouverture A doit avoir à peu près 1 centimètre de largeur. Chauffez au rouge le tuyau ainsi préparé, puis recouvrez-le, dans le sens de sa longueur, de fil de cuivre protégé par du coton ou de la soie, fig. 2. Plus le nombre de tours est grand et plus le fil est fin, plus la force de l'aimant est grande jusqu'à une certaine limite cependants. Avec un électro-aimant ainsi construit, on peut enlever un poids de 100 kilogrammes, en employant une pile de quatre éléments Bunsen seulement.

L'IMPRIMERIE AU JAPON

Les avantages de l'imprimerie à caractères mobiles ne sont plus à établir. Chez les Européens dont l'alphabet se réduit à un petit nombre de lettres, rien n'est plus facile que de former les mots. Mais c'est une tout autre affaire dans les pays qui, comme la Chine et le Japon, ont besoin d'un caractère particulier pour exprimer chaque idée, chaque mot-

1 Voir *Monde de la Science et de l'Industrie*, p. 68, (1re année n° 5).

Pendant tout le temps de notre navigation, nous pûmes causer de navire à navire aussi facilement que si nous nous fussions trouvés dans le même cabinet. Nous croyons même avoir remarqué que le retour par la mer donnait plus de netteté au son.

Depuis, un des officiers du *Iecate*, M. le lieutenant de vaisseau des Portes, a eu la très-heureuse pensée d'appliquer le merveilleux instrument à la manœuvre des scaphandres. On a remplacé une glace du casque par une plaque en cuivre dans laquelle est enchâssé le téléphone; ce qui fait que le scaphandrier n'a qu'un léger mouvement de tête à faire, soit pour recevoir des communications de l'extérieur, soit pour en adresser. On comprend tout l'avantage d'un pareil dispositif.

Nous avons à visiter nos cavènes; les scaphandriers descendent et peuvent nous rendre compte de tout ce qu'ils voient ou font, *sans qu'il soit besoin de les ramener hors de l'eau*, comme cela s'est fait jusqu'à ce jour.

Grâce au téléphone, un homme parcourant les profondeurs des mers peut rester constamment en communication parlée avec son semblable resté à la surface.

LE TÉLÉPHONE

A L'ACADÉMIE DES SCIENCES

Dans la dernière séance de l'Académie des sciences M. du Moncel a présenté deux communications importantes relatives au téléphone; — la première est de M. J. Lavrid qui rend compte des deux expériences suivantes :

1° Dans un électro-aimant creux en fer à cheval, dont la rapidité n'était que de quelques centièmes exiles, j'ai versé une assez grande quantité d'eau pour que les deux extrémités de cet électro-aimant dont horizon, le liquide pût apparaître dans un tube capillaire adapté à l'un des branches. De cette manière les plus petites variations dans la capacité de la partie creuse de l'électro-aimant étaient accusées par une ascension ou une descente de la colonne liquide, or, en faisant traverser l'électro-aimant par un courant électrique interrompu de différente intensité, depuis la plus faible jusqu'à celle de 8 éléments Bunsen, je n'ai observé aucun changement dans le niveau de l'eau dans le tube, et par conséquent, je pouvais conclure qu'il n'y avait aucun changement dans la capacité du réservoir électro-magnétique.

2° Atteignant le résultat négatif précédent à la politesse de mon électro-aimant, j'en ai fait construire un de 30 centimètres de longueur, d'un diamètre extérieur de 40 millimètres et de deux millimètres d'épaisseur. Sa capacité était de 150 c. c. et les deux extrémités étaient fermées avec deux disques de fer dans que y étaient vissés et dont l'un portait le tube capillaire. Cet appareil étant rempli d'eau, j'ai fait passer à travers son hélice magnétisante toutes sortes de courants, et je n'ai encore jamais constaté le moindre changement dans le niveau de l'eau dans le tube. Avec cette disposition, j'aurais pu cependant observer un changement de volume de $\frac{1}{20}$ de millimètre cube, variation qui, dans les conditions de mon appareil, aurait correspondu à celle que produirait dans le même noyau un changement de plus de degré C. J'avais du reste constaté que les parois intérieures du noyau étaient magnétisées.

L'auteur en conclut que les changements magnétique l'action magnétisante dans une masse M. du [illegible] utilis[illegible] dans les téléphones aux vibrations moléculaires dont parle M. de la Rive dans ses Mémoires de 1816, est complétement dans le vrai.

Il ajoute d'autres considérations sur lesquelles nous pensons avoir prochainement l'occasion de revenir.

—

M. des Portes, ayant établi à bord du *Iecate* un circuit d'environ 100 mètres de fil de sonnerie avec retour par la mer, a mis à l'une des extrémités un téléphone Bell, et à l'autre, un aimant de téléphone portant sa bobine et suspendu verticalement par un fil de *soie*, la bobine en haut.

A l'aide de ces dispositifs, il a ensuite exécuté cinq expériences dont il rend compte en ces termes :

« *Première expérience.* — On frappe sur l'aimant transmetteur avec un morceau de bois. Les bruits sont parfaitement distincts au récepteur, et ils augmentent d'intensité à mesure qu'on frappe plus près de la bobine. Si l'on met en contact avec la partie supérieure de l'aimant transmetteur une plaque vibrante ordinaire en fer doux, les bruits entendus au récepteur sont plus forts, mais moins nets. Si, au lieu de bois, on prend un morceau de cuivre pour frapper l'aimant, les bruits perçus sont très-peu *différents*.

« Les effets obtenus dans ces deux cas ne sauraient être que la conséquence du mouvement vibratoire imprimé par le choc à l'aimant, *mouvement d'un certain ordre* que les fils métalliques transmettent à toute distance, s'ils sont dans de bonnes conditions d'isolement.

« *Deuxième expérience.* — On frappe avec un barreau de fer doux. Les bruits entendus au récepteur sont beaucoup plus forts qu'avec le morceau de bois, et, en mettant une plaque vibrante au contact de la partie supérieure de l'aimant, on saisit, en même temps que le bruit du choc, une vibration de la plaque.

« *Troisième expérience.* — On frappe sur l'aimant avec un autre aimant. Les pôles de même nom frappés l'un contre l'autre produisent un bruit semblable à celui du fer doux; mais, si ce sont deux pôles de noms contraires, on entend, après chaque coup, un second bruit produit par l'arrachement de l'aimant et qui paraît être un coup frappé beaucoup moins fort. Les bruits augmentent d'intensité, si l'on met une plaque vibrante au contact de l'aimant. La personne qui est au récepteur arrive très-rapidement à reconnaître [illegible] pour, avec quelle matière on a frappé sur l'aimant.

« *Quatrième expérience.* — Si l'on parle sur une plaque vibr[illegible] mise au contact de l'aimant transmetteur, [illegible] entend au téléphone récepteur des sons, [illegible]bles, assez semblables à ceux que produisent les vibrations d'une corde à violon. Le bruit que fait la plaque vibrante au moment où on la retire du contact de l'aimant est parfaitement entendu au récepteur.

« *Cinquième expérience.* — [illegible] quand on [illegible] au téléphone récepteur, la parole [illegible] appliqué sur la plaque vibrante

Menlo Park Scrapbook, Cat. 1030

No. 19A. "Phonograph"

This scrapbook covers the years 1877-1880 and 1887 and contains clippings about the phonograph. There are 136 numbered pages.

Blank pages not filmed: 76-136.

Guillermo Prieto

EL FONOGRAFO.

Hace dos años, pico mas, pico menos, que andando en New-York de paseo por la parte alta de la ciudad, despues de haber visitado la fábrica de pianos de Steeway, y al doblar una esquina, con un compañero muy querido que me serviá de guia, pasó frente á nosotros un hombre de aspecto vulgar, cargado de hombros, de trajo maltratado y de sapo—to como uno de tantos obreros de los que pueblan aquella parte de la ciudad. El compañero me dijo:

—¿Se fijó usted bien en ese hombre?

—No: apenas llamó mi atencion.

—Volveremos por esta calle para encontrarlo de nuevo.

En efecto, lo cortamos la vuelta al desconocido, y á poco, ponia á su frente el daguerrotipo de mi memoria.

Era un hombre de mas que medianas estaturas, angosto y anguloso, de gran desórden en su trajo, y hasta me pareció distinguir huellas de tizne en su cara. El rostro largo y pálido, el cabello en lacios hilos sobre la frente y bajando á los ojos. La frente resguida en las sienes y como de balcon, con una prominencia saliente muy notable.

Pero lo que realmente me admiró de aquel jóven fué la mirada, iluminada por una claridad y una lluvia futima, como un rayo de sol reverberando en un topacio.

—¿Quién es ese jóven? preguntó á mi amigo sin perder de vista al hombre sobre quien se habia llamado mi atencion.

—No sino á responder á usted si hemos visto á un hombre extraordinario, típico de este siglo de fenómenos sorprendentes, ó un loco desgraciado; pero siempre sorprendente, llamado á sepultar su existencia dentro de pocos dias en *Bluteland*.

—¿Qué me está usted diciendo?

—Ese jóven se llama Eddison, nació en el Ohio, en 1847; de familia pobre, recibió una educacion comun y ganaba su vida vendiendo papeles y repartiéndolos en las calles y los ferrocarriles.

No sé por qué truco alto entró en una oficina telegráfica como uno de tantos dependientes.

Un dia llamó á uno de los directores del telégrafo, y mostrándole uno de los alambres por su parte superior, le dijo:

—Vea usted, por aquí va y viene un mensaje; pues yo creo que por aquí debajo podria ir y venir otro.

Poco esto lo dijo con tal ardor y con un tono tan convencido, que acabó el confidente por temer que saltase por una ventana aquel inventor de nuevo género, y fué despedido Eddison por loco, en virtud de su maravillosa indicacion.

A poco tiempo, como usted ha visto, iban y venian los dos mensajes y van y vienen cuatro, haciendo camino real el alambre, segun y como lo ha visto usted funcionar en la oficina de «Wester-Union Telegraf.»

La realizacion del cuento del loco dividió, respecto á Eddison, la opinion, teniéndolo los unos por génio extraordinario, y aplicándolo los otros el dictado de demente.

Eddison de nada se cuidaba ni parecia hacer caso de la misma madre que lo parió; ensimismando, semibramas, marchando al acaso, sin pretensiones de gran sabiduría ni estudios profundos, visitaba á un amigo, fabricante de pianos, y por vía de tarjeta, y como recuerdo de cariño, le sugirió una modificacion en la estructura de sus manufacturas, que le valió inmenso crédito y valiosas patentes de invencion.

Los que se acercaban á Eddison veian poco menos que con la cabeza trastornada; les hablaba á los unos de subdivisiones de corrientes eléctricas, como si se tratara de hacer tejidos de rayos ó de mecer á un mozito la Catarata del Niágara; es decir, un mar que se despecha á dia se quisiera meter el en el bolsillo ó establecer un carril aéreo para ponernos en contacto con los habitantes de la luna.

No obstante que para mis adentros, si aquel chico no estaba loco, merecia un exorcismo, por tener un diablo de mucha cuenta en el cuerpo, yo ví á aquel jóven con admiracion profunda, no sé por qué, y está fija en mi memoria su rostro, y hasta sus manos de tendones salientes, largas y tiznadas.

Han pasado dos años: la fama prodigiosa del Fonógrafo comenzó á circular en el mundo científico, y el nombre de Eddison se ha colocado en primera fila de esos genios que parecen responder arrogantes al ¿*quién como Dios?* del arrogante vencedor de Satan.

Yo, rudo é ignorante de mio, luego que ví la maquinilla parlante, me dije: esto es cosa de los yankees, espacio de hacer hablar á las piedras cuando se trata de sacar dinero.

Y al llevar la noticia del invento prodigioso á la casa de mis comadres, me decian:

—Oiga usted, Fidel, eso ha de ser cosa de hechizos; vayas usted, por Dios, con mucho tiento, y si lo llaman á usted, lo mas seguro es santiguarse, aunque sea con mucho disimulo, con la señal de la Cruz.

[illegible] por ser la glorificacion de la ciencia.

4

UNA SESION DE FONOGRAFIA

Oct 12/78

EL FONOGRAFO DE EDISON.

Cortesmente invitados por el Sr. Wise, tuvimos tambien el gusto de asistir en la noche del Jueves al ensayo del fundgrafo de Edison.

El acto se verificó en el testro de la Sociedad Nezahualcoyotl; y á su presencia de unas cincuenta personas, en su mayor parte miembros de la prensa de la capital.

Despues del tradicional *Señoras y Caballeros*, el Sr. Wise dió lectura á un discurso, glorificando los grandes conquistas del espíritu humano, especialmente en las aplicaciones de la electricidad. Nos habló del rayo, donado primero como una flora, y convertido despues en humilde mensajero del hombre para llevar su palabra á través de las tierras y de los mares, dirigió dulces quejumbres á la rasa latina, como bicicletadora, á verse, y como perfeccionadora, amenudo, de los grandes inventos científicos, y terminó esta parte de su discurso, solicitando la indulgencia de la sociedad mexicana para los ensayos que iba á emprender del aparato fonográfico.

Trasó en seguida y á grandes rasgos la biografía de Edison. Nació en Nueva York y repartidor de periódicos en los ferrocarriles, fué despues empleado en una oficina telegráfica, de donde se le despidió, porque tuvo el atrevimiento de sostener que un cierto aparato podia conducir simultáneamente dos mensajes telegráficos.

Comenzado desde entonces á sus estudios y y experimentos sobre aplicaciones de la electricidad, tuvo la gloria de alcanzar resultados maravillosos. Halló el medio de trasmitir simultáneamente no solo dos, sino hasta cuatro dispach. a telegráficos por un solo hilo; tiene muy adelantados sus estudios y cuenya para usar de la electricidad como productora de la luz; para emplearla como motor de gran potencia, y para utilizar las grandes caidas de agua, por ejemplo, la catarata del Niágara, á fin de que ofrezcan su fuerza motriz á grandísimas distancias. Por último, á la edad de 31 años, Edison es autor de ciento cincuenta descubrimientos, entre los cuales merecen particular mencion el fundgrafo, el teléfono y el micrófono.

El fundgrafo es un instrumento de extremada sencillez. Consiste en un cilindro metálico de cinco pulgadas inglesas de diámetro en su base por seis de altura, estriado en el sentido de esta, y colocado horizontalmente sobre una barra cilíndrica y estriada á su vez, que le atraviesa, y á la cual imprime rotacion un manubrio. Como las ranuras ó estrías de la barra corresponden exactamente á las del cilindro, la rotacion de aquella imprime movimiento horizontal á este. Sobre el cilindro, se adapta perfectamente una finísima lámina de papel de estaño.

Aunque esta pieza es la mas visible del aparato, podiera decirse que desempeña un papel secundario. El principal corresponde á una lezquilla, (1)a por una barra al pié de sustentacion del cilindro, que corre por delante de ella. A esta lezquilla está adaptada una membrana metálica montada en dos cojinetes de goma, cuyas vibraciones se trasmiten á una aguja, por medio de un delicado resorte.

Hablando en la lezquilla, las ondas sonoras hacen vibrar las membranas; y la aguja va marcando con extraordinaria precision una série de puntos en el papel adaptado al cilindro, al cual se imprime simultáneamente un movimiento, para que corra ante la aguja. Estos puntos son la notacion fidelísima de las inflexiones de la voz.

Pásase en comprobarlo. Colóquese el cilindro en su primera posicion, y la aguja en contacto con la superficie aguijereada, á medida que vaya ser penetrando en los puntos que ella misma trazó, repitiendo las vibraciones, que le fueron trasmitidas, á la membrana trasmisora, y esta á su vez á la columna de aire, formando los mismos sonidos articulados que se confiaron; aunque con grandes diferencias en alturs, intensidad y timbre. Por esto y para aumentar la intensidad, conviene aplicar á la lezquilla, como lo hizo el Sr. Wise, un tubo cónico, que desempeñe, las funciones de una bocina ó porta-voz.

La poca elasticidad del papel de estaño y su facilidad para ceder á la presion, son la especialidad de nuestro oido para apreciar vibraciones de amplitud infinitesimal, por decirlo así, son las agentes que producen esta maravilla. La impresion que la aguja registradora deja en el papel se conserva por las propiedades antedichas, y cuantas veces la aguja pase por ellas la trasmitirá las mismas vibraciones. En cambio, por muy pequeña que sea la amplitud de las vibraciones de la membrana, produce un sonido perceptible, pues lord Rayleigh ha demostrado que hasta para oido un movimiento de un milloncésimo de milímetro.

El *fundgrafo* no es mas que una feliz modificacion del *teléfono* articulado, realizado por el ingenioso y ya célebre M. T. A. Edison, de Nueva York. Sin que pretendamos amenguar el aprecio que merece su invencion, no nos parece fuera de propósito recordar que en 1874, presentó M. W. K. Barlow á la Sociedad Real de Lóndres un instrumento llamado *logógrafo*, fundado en el mismo principio de la reproduccion de las vibraciones sonoras por los cuerpos elásticos puestos en su trayecto. La diferencia sin embargo es notable, pues el *logógrafo* no logra mas que *pintar* la palabra por medio de líneas quebradas y curvas que indicaban el tono, intensidad y timbre de los sonidos.

El Sr. Wise, despues de haber descrito el aparato, se extendió en diversas consideraciones sobre su utilidad práctica: la lámina de estaño puede conservar y reproducir, siempre que se la pida, una aria de la Patti; el esposo ausente puede escuchar á millaresde leguas de distancia la voz de su consorte, grabada en una lámina que le trasmitan las últimas de correos; y el amante puede saborear cuanda le venga en gana, la dulce confesion de amor que unos labios de rosa hayan asomrado únicamente sobre la consabidhoja de estaño.

Procedióse en seguida al ensayo del instrumento, comenzando por el himno nacional, y repitiéndose por espacio de una hora las experiencias. El Sr. Wise platicó con un querido aparato, gritó cuan los vendedores de cuetitos, cerró como los serenos de antaño, bostezó, estiló, y pronunpió en frenéticos hurras y en *carrancleas* que hacian temblar los desatalados corredores de Bellavista; todo esto sin perder un gravedad augusta, y sin arrugarse los paños al descomprenerse el lazo de la corbata blanca.

El Sr. Wise dió por terminada la sesion á las once de la noche, y los concurrentes fuimos invitados á pasar al comedor, donde se habian dispuesto los agasajos. Allí pusimos comentarios á nuestro sabor, y el Sr. Wise llevó su amabilidad hasta el extremo de colocar una nueva hoja de estaño para que no apreciara de cerca el mecanismo del instrumento. D. Clemente Villaseñor y algunos otros artículistas dijeron frases que la aguja fonográfica anotó con maravillosa exactitud; bastaba (4) A. Alegría, mustió una cancion endemoniada, y, por último, el jóven Calva recitó una bonita octava real, glorificando al inventor del fonógrafo. Todo, incluyendo la cancion satánica, fué reproducido por el *fundgrafo*, y con esto terminamos los ensayos, por los cuales felicitamos cordialmente al Sr. Wise, deseando al mismo tiempo los ejemplos de la afabilidad y cortesanía con que se sirvió sotisfacer á todas nuestras preguntas sobre el maravilloso instrumento que ha venido á exhibir entre nosotros.

Y ahora, aventuremos dos observaciones. Sea la primera que, al verificarse la reproduccion de los sonidos, se hace perceptible al mismo tiempo cierto runnrullo sordo, profundo tal vez por el movimiento de rotacion que no limpian á los cilindros. Creemos que este pudiera remediarse fácilmente; y sea segunda que, al bien el Sr. Wise posee el idioma castellano, no puede articularlo con toda precision y claridad, y estas imperfecciones, aumentadas en la reproduccion de los sonidos hecha por el fonógrafo, alcanzan el efecto que produce el instrumento de Edison. No permitimos, pues, insinuar al Sr. Wise que para sus sesiones públicas se procure el auxilio de algun actor de buena voz y de articulacion limpia y correcta.

¿Y el teléfono y el micrófono de Edison?..... Paciencia; ya nos avisará el Sr. Wise cuando se verifica el primer ensayo, y de nuevo relataremos cuanto á nuestros lectores.

Prensa

EL FONOGRAFO. Oct 15/78

Admirados nos dejó el viérnes pasado, el ensayo del fonógrafo, en el teatro de Nezahualcoyotl; de ese aparato que tan bien escribe y reproduce la voz humana, la música, el canto y toda especie de sonidos. La funcion fué precedida por un buen discurso leido por Mr. Heredales, sobre los diversos descubrimientos alcanzados por el genio americano de Mr Edison. Despues varios experimentos invirtieron lugar y concluida la sesion, los diversos miembros de la prensa que concurrieron, fueron á hacer que el maravilloso aparato reprodujera sus gritos, sus cantos y sus juegos de palabras.

Los Sres. Wenzel y De Gante, 1, de Plateros, núm. 5, son los únicos agentes en México del fonógrafo y teléfono de Edison.

El dia 10 del actual tuvo efecto un acontecimiento bastante significativo para el mundo científico. Me refiero á la cátedra experimental, que próvia invitacion á todos los miembros de la prensa, hizo ante ellos, el fonógrafo, teléfono y micrófono, en el cuadro, ameno elegante teatro de la sociedad Nezahualcoyotl, el Dr. E. C. Wise.

Cincuenta ó sesenta individuos, pertenecientes casi todos al periodismo científico, presenciaron la experiencia, que dando poco menos que admirados unte el poder intelectual del hombre.

Y eso poder qué hace hablar á los sires inertes para importante para despertar la conciencia dormida de los relatorios al patriotismo y á la dignidad? Creo que no; porque esperar que la diputada de la Cámara de diputados, por honor propio, se convertirá en mínima é insignificante minoría.

Tabi. Oct 15/78

CHARLA DE LOS DOMINGOS.

El fonógrafo del fonógrafo!

Por fin ha llegado á México el admirable aparato que reproduce la voz humana. El jueves último la prensa fué invitada á la primera audición del prodigioso invento; interesantes fueron los experimentos practicados, y de ellos pasamos á dar cuenta á nuestros lectores.

En el salon de la sociedad «Netzahualcoyotl,» estaba reunida una regular concurrencia, ante la que se verificaron las pruebas más concluyentes. En la escena, veíase el retrato de Edison, el jóven inventor; al frente sobre una mesa estaba el fonógrafo, y de uno y otro lado el micrófono y el teléfono, todo debido al genio de ese hombre extraordinario.

La sesion comenzó por un discurso del Sr. Eduardo Wise, que en seguida insertamos, y cuya lectura no podemos ménos que recomendar, porque encierra la historia del inventor y sus grandiosos proyectos para el porvenir.

El Sr. Wise comenzó por un breve exordio, pidiendo la indulgencia de su auditorio, y en seguida dijo:

* * *

Este siglo ha sido fecundo en sus maravillosos descubrimientos é invenciones.—Cantaremos de prodigios en prodigio cada dia de nuestras nuevas pruebas de que es verdaderamente el Rey de la Creacion.—Por todas partes la naturaleza se somete á sus mandatos, y las leyes fieles esperan sus órdenes para servir á sus necesidades, sus caprichos. Un dia encadena un rayo, como quien sujeta una fiera, hoy le maneja á su placer, y la confia sus pensamientos para que los lleve á través de tierras y mares, y el relámpago le obedece como un cordero.

Tengo el honor ahora de presentar ante vdes., una [illegible]-traccion práctica de algunos aparatos del inventor Cesaneable, más grande y más notable de la época.—El Sr. Tomás A. Edison—Tendré el gusto de exhibir ante vdes., esta noche, algunas de las invenciones de este señor, cuplicando al indulgente público me dispense, si no soy capaz de hacer justicia al eminente inventor.

Unas cuantas observaciones pueden demostrar, cómo un jóven, en unos cuantos años, ha conseguido más, que lo que han podido soñar los sábios antiguos, y aun los modernos, con la instruccion del siglo.

El Sr. Tomás A. Edison, comenzó su vida como casi todos los grandes hombres de los Estados-Unidos. Nació en el Estado de Ohio en 1847, de padres humildes y honrados, y no hay sinó una edad en la que el Sr. Edison no haya principiado á dar cuenta á nuestros lectores.

En el salon de la sociedad «Netzahualcoyotl,» estaba reunida una regular concurrencia, ante la que se verificaron las pruebas más concluyentes. En la escena, veíase el retrato de Edison, el jóven inventor; al frente sobre una mesa estaba el fonógrafo, y de uno y otro lado el micrófono y el teléfono, todo debido al genio de ese hombre extraordinario.

La sesion comenzó por un discurso del Sr. Eduardo Wise, que en seguida insertamos, y cuya lectura no podemos ménos que recomendar, porque encierra la historia del inventor y sus grandiosos proyectos para el porvenir.

El Sr. Wise comenzó por un breve exordio, pidiendo la indulgencia de su auditorio, y en seguida dijo:

* * *

Este siglo ha sido fecundo en sus maravillosos descubrimientos é invenciones.—Cantaremos de prodigio en prodigio cada dia de nuestras nuevas pruebas de que es verdaderamente el Rey de la Creacion.—Por todas partes la naturaleza se somete á sus mandatos, y las leyes fieles esperan sus órdenes para servir á sus necesidades, sus caprichos. Un dia encadena un rayo, como quien sujeta una fiera, hoy le maneja á su placer, y la confia sus pensamientos para que los lleve á través de tierras y mares, y el relámpago le obedece como un cordero.

Tengo el honor ahora de presentar ante vdes., una [illegible]-traccion práctica de algunos aparatos del inventor Cesaneable, más grande y más notable de la época.—El Sr. Tomás A. Edison—Tendré el gusto de exhibir ante vdes., esta noche, algunas de las invenciones de este señor, cuplicando al indulgente público me dispense, si no soy capaz de hacer justicia al eminente inventor.

Unas cuantas observaciones pueden demostrar, cómo un jóven, en unos cuantos años, ha conseguido más, que lo que han podido soñar los sábios antiguos, y aun los modernos, con la instruccion del siglo.

El Sr. Tomás A. Edison, comenzó su vida como casi todos los grandes hombres de los Estados-Unidos. Nació en el Estado de Ohio en 1847, de padres humildes y honrados, y no hay sinó una edad en la que el Sr. Edison no haya principiado á dar cuenta á nuestros lectores.

Continuó sus investigaciones no solamente en teoría, sino prácticamente. En muy poco tiempo consiguió desquitar hasta cien mil pesos en cualquiera direccion por el mismo alambre ó conductor. Este estableció su reputacion. Una invencion siguió á la otra sucesivamente. Hasta hoy el mundo civilizado debe al Sr. Edison más de 150 invenciones, todas científicas, y que marcan el adelanto del siglo y la grandeza de su inteligencia, por ejemplo, el teléfono, el micrófono, el megáfono, el aeróligno, la pluma-eléctrica, y como si esto no bastara, ha venido por último Mr. Edison, y ha inventado el fonógrafo.

El fonógrafo sirve para conservar los sonidos, sean ó no articulados ó artículados; de manera que no solo los reproduce una vez, sino que los reproduce cuda vez que uno quiere poner en accion el aparato. Este guarda la palabra como una arca cualquier objeto, y no hay más que abrirla para encontrarlo. Los experimentos hechos con el fonógrafo ante la Academia de ciencias de Paris y el Instituto real de Lóndres, y en presencia del prodigio, los sabios acadé micos no pudieron dominar su entusiasmo y rompieron en aplausos atronadores.

En la gran Exposicion Internacional de Paris, la comision científica le regaló una medalla de oro, como el inventor más notable de la época.

De sus últimas invenciones, el teléfono y el fonógrafo, pueden considerarse entre las más elevadas. Son unos futuros y sus importancia no pueden ser apreciados actualmente. Segun las últimas noticias recibidas del Sr. Edison, sabemos que ha logrado la aplicacion del gran problema de aplicar la electricidad para producir la luz, y como un motor para la maquinaria más extensa.

Hasta ahora los científicos más distinguidos solo han podido dividir la luz eléctrica en diez partes. El Sr. Edison ha descubierto la manera de dividirla en diez mil luces. Tambien porque utilizar el poder de las cataratas ó cascadas, ríos, etc., que ahora se pierde, por medio de la electricidad; y se dice que por este medio, el poder de cien millones de toneladas de agua que se precipitan en el abismo del Niágara cada hora, con una caida de ciento cincuenta piés, se podria trasmitir, por medio de la electricidad en todo el Estado de Nueva-York para mover la maquinaria de la fábrica de Valiant, que emplea 300 hombres, y que dista del rio la cantidad pierde de una milla, y se dice que en esta trasmision solo se pierde 20 por ciento del poder del rio.

Tengo el placer de presentar á vdes., finalmente, el fonógrafo. Este aparato es prodigio la voz humana, el canto, silbidos y

la música instrumental—la voz humana, sea cantando ó hablando, ó cualquier otro sonido; no solo lo repite por una sola vez, sino por todas cuantas veces se desee ya sea ahora, ó dentro de un mes, un año ó un siglo.

Este aparato, tan sencillo, reproduce la voz humana por medio de la insculpcion,—resultado deseado por tanto tiempo, y lo que no han podido lograr miles de hombres de la más alta inteligencia, despues de muchos años de estudio.

Me propongo ahora demostrar prácticamente los trabajos de este aparato, siguiendo el programa, y empezemos con el Himno nacional.

Ahora tenemos grabado el glorioso Himno nacional en una lámina delgada de estaño (como esta) por medio de un disco, cuyo diafragma vibrante contiene un pequeño punzon, puesto en movimiento por la vibracion de la voz, y dando al mismo tiempo vuelta al cilindro para recibir la impresion de los sonidos en su órden.

Para reproducir este Himno nacional, palabra ó sonido cualquiera, no se requiere más sino que el punzon vuelva á recorrer su mismo camino. El punzon, al pasar sobre las impresiones anteriormente causadas por la voz, pone en vibracion otra vez el diafragma, y de consiguiente reproduce el mismo sonido, como vdes. oirán en seguida. (Repeticion del Himno nacional por el fonógrafo.)

En seguida continuaremos con algunos experimentos prácticos. (Se hicieron los experimentos.)

Como dije antes, esta invencion está en su infancia é en embrion. Este aparato simplemente hasta un principio hemos hace muchos años, y al fin encontrado por el Sr. Edison.

Imaginemos que se pueda hablar por medio de esta pequeña lámina de estaño, mandándola en un sobre por el correo á un amigo, á miles de leguas distante, quien podrá, agitándolo en su máquina, oir de viva voz lo que se le dice.

Dentro de pocos años de la fecha este aparato le podrá estar en toda familia.

Ayudará al esposo, cuando tenga que viajar, á dejar sus instrucciones á su esposa. Ayudará á un enamorado para hablar á su amante sin verla, y ella podrá oir sus palabras de amor cuando lo desee.

Las más sublimes canciones é melodías de la Penatini ó de Adelina Patti podrán mandarse como una carta á cualquier punto del mundo. No tienen ya los usos á que este simple aparato podrá aplicarse dentro de pocos años!

Tambien tengo el honor de presentarles el teléfono del Sr. Edison. Este instrumento hará desaparecer al telégrafo,—como existe hoy, en pocos años, y aun hoy existe en uso general en Nueva-York y otras grandes poblaciones, especialmente para los cambios de bierro, banqueros, comerciantes, etc., y como comunicacion particular.

Hay varios teléfonos construidos bajo distintos principios. El teléfono de Bell, como el colocado entre Chapultepec y el Paseo, depende de una magnesia para conducir sonidos, mientras que el pretendo que la invencion del Sr. Edison es enteramente original, pensado únicamente en un disco de carbon, del tamaño de una peseta, que sirve para trasmitir la voz. Debo decir á vdes. que el descubrimiento del Sr. Edison, de la propiedad y sensibilidad del carbon, es una de las maravillas del siglo—casi todas las invenciones, como el micrófono, dependen de esto.

Con este aparato, la voz ó cualquier sonido puede ser trasmitido á 500 ó 1,000 millas.

Este precioso aparato es el micrófono y teléfono combinados; hablando por conducto de esta boquilla, aunque sea á tres ó cuatro pies de distancia, se pueden oir á 20 ó 40 millas, clara y distintamente todas las palabras que se digan.

Imaginemos que un padre haya colocado un pedazo de carbon en la sala, en donde su hija tiene una entrevista con su amante. (Ahora sorprenderán no quedarán ciegos al saber que él, en su recámara, está al tanto de toda la conversacion entre los dos amantes por medio de su micrófono! Si no lo creen, usad el carbon y lo verán.

* * *

En seguida principiaron las esperiencias, un caballero cantó el himno nacional entre la pequeña bocina del aparato, y este lo reprodujo con toda fidelidad, pero perceptible, nada se perdia de la cadencia de la música, y las palabras del canto se conservaron asimismo.

Despues el Sr. Wise habló varias veces, el fonógrafo reprodujo sus palabras repitiéndolas con toda claridad. En seguida á la bocina una corneta, tocó una diana, el aparato la devolvió perfectamente; se imitaron los gritos de diversos animales, se tararon canciones, silbidos, se tocó por medio del piston la marcha de Aida, y por último, se agruparon gritos, silbidos y música; todo se reprodujo con la vibracion de la delgada lámina de estaño que, grabados en pequeños puntos, conserva las inflexiones de la voz.

El invento está en la infancia y no pero deja de ser maravilloso la voz se escucha débil pero se percibe clara, y cuando las palabras se pronuncian bien y fuerte, entonces el aparato las devuelve con notable perfeccion. La concurrencia aplaudia entusiasmada á cada nueva prueba.

Porque en preciso admirarse delante de aquel maravilloso aparato que ya cantaba, ya hablaba, ya silbaba, y remedaba los gritos de los animales, todo con gran fidelidad.

El problema está resuelto, el complicado aparato de la laringe humana, está ahí convertido en un rodanito, un cilindro y una agnia insertada sobre una lámina de talco; la dificultad que en contra de el fonógrafo [illegible] como todos los inventos, se sencillo en sus construccion y fácil en sus diversas aplicaciones, [illegible] de [illegible] de la [illegible] que todavia [illegible] máquina [illegible] [illegible] [illegible]

prerenciado no pueden ser más satisfactorias, porque debe decirse que asistimos á la infancia del aparato, y tal vez puede que también esta reciente práctica para manejarlo, y que á favor de ella los resultados deben ser más brillantes todavía.

De todas maneras nos cabe la satisfacción de haber visto y escuchado á la maravillosa máquina que en estos momentos es la admiración de Londres y París. México también ha tributado ya un homenaje de respeto al genio de Edisson, le ha aplaudido, le ha enviado al través de la distancia el más sincero y entusiasta parabien.

Los Sres. Wise y Bardisco se proponen dar algunas sesiones de audicion del fonógrafo en el mismo teatro de la Netzahualcoyotl. Suponemos que acudirá una numerosa concurrencia, porque el objeto vale bien la pena, el aparato es digno de verse; todo lo que pudiéramos decir á nuestros lectores es poco; hay cosas que es necesario palpar las para creer en ellas.

Cuando hace algunos meses nos llegaban las primeras noticias del fonógrafo, sonreíamos con desdén creyendo que no trataba de algun *humbug* americano; mas cuando los mas sabios las avalaron con los cuerpos científicos han intentado al inventor, y sobre todo, cuando hemos visto y oido el aparato, no hemos podido ménos de abismarnos en la contemplacion de tanto, el vuelo que alcanza la sublime inteligencia humana, y de todos los adelantamientos que verifica nuestro siglo.

La voz de nuestros dias.

Obsequiando la invitacion que el Dr. E. G. Wise hizo á la prensa para que asistiese el jueves en a noche al teatro de la «Sociedad Nezahualcoyotl,» donde iba á pronunciar un discurso científico y hacer una prueba práctica de... el fonógrafo, microfono y fonógrafo del renombrado Edisson, fuimos, y ocupamos un asiento en uno de nuestros palcos de los espectadores. No nos arrepentimos, sino que, por el contrario, quedamos satisfechos de no haber faltado á la cita.

¿Quién no sabe á la ciencia? ¿Quién no asiste á sus triunfos, y celebra y aplaude como propias sus victorias? No tiene duda que el siglo XIX vive en gran intimidad con la naturaleza física, y que este premia el trabajo de las inteligencias que solo consagran, abriéndoles el *sancta sanctorum* de sus leyes y revelándoles el misterio de sus secretos.

Cada dia se suceden unos á otros nuevos inventos, que sobre ser asombro y maravilla del mundo, motivo de gloria, de inmortalidad y de fama del inventor, es para los demas un particular y para la sociedad en general, un medio de que se sirven para adelantar un paso siquiera en el áspero y difícil camino de la perfeccion intelectual, y á la vez un elemento que explota de mil suertes y con múltiples fines, al grado de convencerse de que casi no hay imposibles para el hombre en el reino de la materia. Dios le entregó el mundo, no solo para que lo dominase como rey, sino para que con sus investigaciones, con sus estudios y aún con sus controversias, crisas á hiciese brotar en él otra luz ese no fuera la del sol, pues el sol ilumina los cuerpos, es su esplendor; pero no puede ilustrar las almas, ni ser su antorcha.

Los tres aparatos científicos que hemos nombrado son un testimonio brillante de hechos que en épocas mas remotas del pasado, se habrian negado por absurdos, ó puesto en duda por inexplicables. Cada uno de ellos habria bastado para honrar á su siglo, á una nacion entera.

Hoy los tres juntos son preciosos engastes de una corona, en que resplandecen otros ciento de mayor ó de igual estima. Edisson, jóven aún, pues apénas tiene treinta y un años, ha hecho con la electricidad, lo que tantos sábios como le han precedido no se habieran atrevido ni á soñar. Con ella ha logrado trasportar la palabra á una distancia de quinientas millas, sin que los instantes le aventajen en rapidez. El teléfono, es una prueba de ese increible portento. Con ella se ha aumentado la intensidad de los sonidos, á fin de que, no por ser imperceptibles, se escapasen á la observacion. El ruido que hace una mosca cuando vuela, ó cuando se posa en nuestros cabellos, bajo la audicion por medio del *micrófono*, parece el estruendoso aleteo de un condor que desde la altísima cumbre de los Andes, se precipita sobre nosotros y se nos acerca, ó una herrada caballgadura, la que pone en planta en nuestra cabeza. Con ella ha alcanzado á escribir la palabra y los sonidos concertados en el bronce, y hacer que la escritura sea una verdadera lengua que habla al oido, y los signos acústicos á notas de la nueva gama musicos instrumentos que toquen á la voluntad alegres sonatas y sublimes pinturas.

El lector se ha menester para leer lo escrito, de haber aprendido el alfabeto, ni los amantes de la armonía para concurrir con las bellezas de Euterpe, necesitan haber cursado las aulas del Conservatorio. Todo mortal, en el hombro sobre la tierra, manos su voz, que depositada en una lámina de estaño y en otra de oro, podrá hacerse oir dos siglos despues de haber sido llevadas á la sepultura los labios y el sér querido que la pronunciaron. Inaudito prodigio! testimonio maravilla! Gloria á la ciencia! Loor y gloria á los cultivadores incansables de la ciencia.

* * *

El fonógrafo fué el aparato que mayor sorpresa causó en los concurrentes. Si no la concitaran nuestros lectores acompañaremos su descripcion, y diremos algo sobre la manera con que obra. Es efecto, es para sorprender.

El aparato repitió sin perder una sola palabra los parabienes que le acababa de dar el Dr. Wise, personificándolo; el himno nacional cantado por Quesada, la marcha de Aida tocada en el piston por no sabemos quién, y varios de nuestros toques militares, sonidos en el clarin. Lo oimos silbar con Emilio Duran, y reir alegremente, ladrar y cacarear con Calderantes, no, el autor del Q. Pito, sino un gallinero de la calle de Zuñiga. Lo escuchamos mandar una batalla con la voz de un general que podria encontrarse del otro lado del oceano. Reprodujo la algazara de una zambra mechuitombre, en la que unos rian y otros lloraban; unos hablan y otros cantan; unos se alaban y otros se llenan de vituperios; unos estornudan y otros gritan desaforadamente.

Aunque todos los trabajos del fonógrafo nos dejaron satisfechos, á decir verdad, no le creemos tan diestro para los sonidos articulados como para los concertados. El fonógrafo es más músico que parlante, ó nosotros más parlantes que él.

Volvamos á repetir: gloria á la ciencia! ¡Loor y gloria á los cultivadores de la ciencia! ¡Loor y gloria al inmortal Edisson!

EL FONOGRAFO DE EDISON.—Pro-

Anticipamos en nuestro número de ayer ocuparnos hoy de la sesion fonográfica con que el Sr. Dr. Eduardo Wise obsequió anteanoche, en el teatro de la Sociedad Netzahualcoyotl, á la prensa de la capital, y sin presunciones y divertidas inconsecuencias, hemos, al fin que nos proponemos, pasmos á llenar ese compromiso.

A las ocho y media se hallaban reunidos en el salon un gran número de periodistas y otras personas distinguidas que, deseosas de conocer el nuevo invento de Mr. Edisson, se habian dado cita allí, correspondiendo á la amable y atenta invitacion del Sr. Wise.

Pocos minutos despues se presentó en la plataforma el jóven doctor americano Sr. Wise, y dió lectura á un discurso que versaba sobre los grandes conquistas de la inteligencia humana, y muy particularmente sobre las aplicaciones de la electricidad.

Hizo tambien una breve reseña biográfica de Mr. Edisson, quien nacido de humildes padres, en la ciudad de Nueva-York, pasó los primeros años de su vida vendiendo periódicos en los estudios de ferrocarril para seguir la ocupacion, cuya hasta cierto punto, no con formaba las aspiraciones de la gigantesca alma del que mas tarde debia prestar grandes servicios á la humanidad, con su asombrosa invencion, y al niño Edison logró un lugar en una oficina telegráfica, donde se dedicó al aprendizaje del arte de Samuel Morse.

Trascurrido muy poco tiempo, concibió la idea de trasmitir á la vez dos diferentes telegramas por un mismo alambre, y al revelar sus pretensiones á su superior, éste lo tuvo por loco, y en medio de la burla de sus compañeros, tuvo que abandonar aquella oficina.

Como todo hombre de talento, poco ó nada se preocupó esta nueva decepcion, y con mayor entusiasmo se dedicó á sus estudios, al grado de lograr trasmitir algunos telegramas por un solo alambre telegráfico.

Entre los muchos descubrimientos que ha dado al mundo son, quizá, los principales el teléfono, el micrófono y el fonógrafo.

Habiéndonos de este último, que es el que tuvimos ocasion de conocer en la sesion de anteanoche.

Consiste en un pequeño cilindro metálico puesto horizontalmente sobre una barra tambien cilíndrica, á la que en el extremo de mas pequeño de su mandrin. Sobre el mandrin se extiende una delgada lámina de estaño, en la que se van grabando una serie de puntos pequeños, que marca una aguja, á la que transmiten vibraciones la membrana de una boquilla fija al pié de sustentacion del cilindro.

Al hablar en la boquilla se ondes sonoras hacen vibrar la membrana esta imprime á la aguja á donde va sujeta. En puntos de que hemos hablado, y al volverse á colocar la aguja en el mismo punto que estaba al empezarse á hablar, el fonógrafo, puesto en movimiento, repite palabra por palabra, sonido por sonido, con una exactitud verdaderamente fabulosa, que la admiracion que en esos momentos inspira la inteligencia humana, va creciendo gradualmente.

Volvamos á la sesion.

Despues del discurso del Sr. Wise, el Sr. Quesada cantó sobre la boquilla del fonógrafo nuestro entusiasta himno nacional, que repitió fielmente el nuevo aparato, y la concurrencia aplaudió en una nutrida y prolongada salva de aplausos.

La voz del fonógrafo es fuerte y si se quiere sonora; con frecuencia se nota en ella cierta confusion que hace ininteligibles algunas palabras; pero esto, segun lo manifestó el mismo Sr. Wise, depende de la poca regularidad con que hacia girar el cilindro la persona que lo manejaba, siendo á veces el movimiento mas precipitado que otras.

No obstante, entre ya hemos dicho, el himno nacional y algunas otras piezas que cantó el Sr. Quesada, fueron reproducidas por el fonógrafo con una perfeccion admirable.

El Dr. Wise hizó repetidas veces en el fonógrafo, y en la reproduccion de sus discur-

los notamos poca claridad y hasta algun confusion, tal vez por los ligeros é inevitables defectos de que adolece su pronunciacion castellana; lo que nos hace creer que el fonógrafo se adapta mejor al español que á cualquier otro idioma extranjero, sin duda por su extremada sonoridad, pues la misma confusion notamos cuando al Sr. Wise dijo algunas frases en frances, inglés ó aleman.

Concluida la sesion, los concurrentes fueron invitados á pasar á la piñonferos para examinar aquel maravilloso aparato.

Estos actos tendrá lugar una sesion públicas, cuyo precio de entrada es un peso, y recomendamos á nuestros lectores no dejen de concurrir á ella, pues seguros estamos de que pasarán un rato sumamente divertido en el elegante salon de la sociedad Netzahualcoyotl.

UNICOS AGENTES

TELÉFONOS, FONÓGRAFOS Y MICRÓFONO.—LO QUE SE TIENE QUE OIR.—LO QUE OIR-SE NO DEBIERA.—ESCENAS FONOGRÁFICAS —HISTORIA DEUN CRITERIO.—PELIGROS DEL FONÓGRAFO.—MANÍA DE LAS FARO-LAS.—DE LOS MONUMENTOS.—DE LOS JARDINES.—DE LOS EUCALIPTOS.—DE LOS FERROCARRILES.—TODOS CONTENTOS Ó SEA LA JIRA DE NOS.—ASCENSION DEL SR. ALEXAE.—LA SOMBRA DE D. FERNANDO. —LA CARIDAD.—DE D. COSME.—EL CACOS.—TEATRO HIDALGO.—TEATRO ARDEU.

¡Oh tiempos y oh costumbres! dijo un filósofo, y yo, con el deseo de *fonografiar*, lo repito.

Hace unos cuantos meses los periódicos dijeron y volvieron á decir que habia un nuevo descubrimiento; el del teléfono; despues vino la noticia del fonógrafo y por fin la del micrófono.

Aquellos tiempos felices, nosotros sin teléfonos, fonógrafos ni micrófonos, oiamos claro y distintamente las voces de los afamados artistas que con la Patti-ni vinieron: oiamos las melodías agradables de la orquesta; oiamos las dulces voces de las hermosas que al teatro concurrian, y hoy ¡oh suerte mil veces impia! hoy que poco hay que desear oir, se nos presenta el fonógrafo que por lo que se vé no es mas que un utilidor y no de grandes dimensiones, en derredor del que se extiende una lámina de metal, por cierto bastante dulzada, estando en contacto con éste, una punta ó lengüeta palpadña qué hace vibrar la voz.

¿Pero qué voces hace vibrar? no la de la Peralta cantando, no la de la Pezzana declamando, sino la de algunos que pondrán las fuerzas agarrocera, la de otro que dice que hace frio, la del de mas allá dí guien le picó una pulga.

Por otra parte, convenid conmigo en que el fonógrafo llega al mundo en el momento y época mas inconvenientes: pues será de nosotros el dia que este instrumento terrible se propague! Puesto en el congreso nos dirá que el diputado N., que hoy pone al pian de Tacuyos, por ejemplo, sobre los cuernos de la luna, mañana lo pondrá bajo las pezuñas de los caballos; llevado al hogar dirá á la esposa los rasgiieros que en su ausencia prodigó al marido á la criada; repetirá el *angel mio*, de la recien casada á la esposa á quien ya el marido llama *demonio*; dirá al esposo tierno lo que su mujer dijo al amante. Yo os digo, os repito, os anuncio á que no llevais á vuestro hogar el peligroso instrumento. Tened la conviccion de que la vida es tolerable á causa de que nuestras pincelladas van mezcladas con un poco de olvido, y figuraos que cuando vais olvidando, obligais al fidelísimo fonógrafo á que os repita lo que os hace mal.

Hace poco tiempo que un enamorado habia ido á ver á su novia á la casa de ésta; se le condujo al salon en que estaba preparado el repetidor instrumento, pero el jóven no lo sabia, la novia entre tanto se pintaba en el tocador y el adorador esperaba.

Un cedrillo albergado indebidamente en el vientre del jóven, hizo sentir á éste el deseo de recobrar la perdida libertad; mas tuvo miedo se vió solo y no encontró un sério inconveniente en libertar al cautivo, y éste salió dando un suspiro tan sonoro como prolongado al verso libre; momentos despues apareció la jóven con un efecto la mas bella pintura, digna del pincel de Rafael ó Miguel Angel. Despues del saludo y de los besos de rigor, pasaron al mayor salon, donde estaba el instrumento y lo hizo repetir. Mientras la voz metálica repitió en todas sus inflexiones el suspiro del cedro.

Yo supongo á todos mis lectores de talento, y es seguro, en consecuencia que piensen por cinco minutos solamente en lo peligroso de tener en casa un fonógrafo. No; hoyos debe llevársela al viento, y hoy tanto mas; hoy que ya ni se escribe, por temor de que lo escrito escrito quede.

LOS INVENTOS

DEL SR. TOMAS A. EDISON.

EL FONÓGRAFO,
EL TELÉFONO

Y EL MICRÓFONO.

Sesion de experimentos y pruebas prácticas, celebrada en la noche del juéves 10 de Octubre de 1878, en el teatro NETZAHUALCOYOTZL ante los representantes de la prensa mexicana y varios hombres científicos, por el DR. EDUARDO CLAY WISE y el DR. F. A BEARDLEE.

El siglo en que vivimos—dijo aquí el sabidísimo inventor con caracteres indelebles en los registros de la historia, ha dicho Flammarion:

La tierra está trasformada.

No por el *milagro* de Josué.

No por las lenguas de fuego de Pentecostes.

No por el paso del mar Rojo.

Está trasformada por los pesados marillos de la industria, por el rechino de las cizallas de hierro, por el silbido del vapor, por el conductor del pensamiento, por las sondas de Paterson, por el rédio-sendro, por el telescopio y el *sextor* de los siglos futuros.

¡La tierra está trasformada!

¡No es Carlo Magno quien la lleva en su manga!

Es el compas del geómetra, el hélice, el dragon flanjuero de la locomotora, el telégrafo que nos permite contar en un minuto la pulsacion de la humanidad entera; por el *fonógrafo* que reproduce eternamente y de viva voz, nuestras palabras, nuestros discursos, nuestros suspiros, nuestra risa y aún el canto que sale de nuestro pecho. ¡El *fonógrafo!* que repite por centenares de años y un número ilimitado de veces la voz de los que ya no existen y el sonido de la bocina que dió la voz de ataque á un sitio de batalla, de triunfo, de victoria!

Es el fonógrafo que hará perfectamente hablar á una distancia de 600 millas ó mas, con un Parisino, un Americano, cuya voz escuchamos ó cuyas palabras oimos como si estuviera a nuestro lado habladonos al oido.

No estamos trasformandos en nosotros mismos, sino en lo que nos rodea, en lo que vivimos, en el medio que habita nuestro ser físico, moral y material. Estamos trasformandos por el *Microfono* que nos hace oir las palabras que se han hablado á una distancia que se ha tocado en cualquier lugar de una pieza distante 20 millas del lugar en que vivimos; el zumbido de un insecto, la pisada de un visitante ó la conversacion de dos ó mas personas; estamos regenerados por los grandes adelantos de la ciencia.

Dejaremos para otra ocasion cuanto pudiera decirse de estos preciosos inventos con que ha honrado al Siglo presente el inteligente Sr. Edison, y sin comparos con la extension que desafianos de la primera sesion de *Fonógrafo* ó máquina de hablar, que hemos presenciado en Méxieo, presentamos á los lectores del *Combate* el discurso científico que en esos momentos pronunció el Sr. Dr. Wise, con motivo del espresado prodigio de que fué invitada la prensa de esta capital, y algunos hombres de ciencia.

Há aquí el discurso de nuestro amigo y compañero el Dr. Wise, á cuya amabilidad debemos el poderlo comunicar á los lectores de nuestro periódico.

Señores:

Al presentarme por primero vez ante la respetable é inteligente sociedad mexicana para tratar sobre una materia científica, y en una forma á mi entender sin precedente en este pais, no se me ocultan las dificultades que deberé vencer si mi discurso ha de ser inteligible y agradable á la mayoría de la concurrencia que bondadosamente se ha reunido para escucharme en la noche de hoy.

No mi desconfianza, sin embargo, ni mi defectuosa elocucion, ni mis pocos conocimientos en el bello, suave y expresivo idioma castellano; cuanto desde luego con la importancia de la materia, por una parte, y por la otra con la tradicional y caballerosa indulgencia que tanto ha distinguido y distingue á la raza latina en donde quie-

ra que la humanidad en suerte constituirse en Nación.

Este siglo ha sido fecundo en sus maravillosos descubrimientos é invenciones.

Continuamos de prodigio en prodigio; cada día dá un hombre nuevas pruebas de que es el verdadero el rey de la creación.

Por todas partes la naturaleza se somete á sus mandatos y las leyes físicas esperan sus órdenes para servir á sus necesidades, sus placeres ó sus caprichos. Un día sucedió el rayo, como quien sujeta una fiera; hoy la maneja á su placer y le confía sus pensamientos para que los lleve á través de tierras y mares, y el reló pago le obedece como un cordero.

Tengo el honor ahora de presentar ante vdes. la prueba práctica de algunos aparatos del inventor incansable, más grande y más notable de la época—el Sr. Tomás A. Edison—Tendré el gusto de exhibir ante vdes. esta noche, algunas de las invenciones de este sabio, suplicando de antemano al indulgente público, me disimule si no soy capaz de hacer justicia al eminente inventor.

Unas cuantas observaciones pueden demostrar cómo un jóven, en unos cuantos años, ha conseguido más que han podido soñar los sábios antiguos y aún los modernos con la ilustración del siglo.

El Sr. Tomás A. Edison, comenzó la vida como casi todos los grandes hombres de los Estados-Unidos. Nació en el Estado de Ohio, en 1847, de padres humildes y honrados; tiene apénas 31 años. Logró obtener la edución primaria. Vendió periódicos en el trayecto de los caminos de fierro, y despues entró en una oficina telegráfica, para aprender la profesion; de esta oficina fué despedido porque inició la idea de que dos mensajes podian despacharse al mismo tiempo, por el mismo alambre. Fué considerado por este motivo, inútil en materia de la electricidad y sus usos. Esto no le hizo desmayar; continuó sus investigaciones, no solamente en silencio, sino privadamente. En muy poco tiempo adelantó bastante, hasta conseguir mandar un mensaje á distancia por el mismo alambre ó conductor. Esto estableció su reputacion. Una invencion siguió la otra sucesivamente hasta hoy; el famoso diplomado debe al Sr. Edison más de ciento cincuenta invenciones, todas científicas, que merecen el adelanto y la grandeza de su inteligencia; por ejemplo: el Teléfono, el Micrófono, el Magnófono, el Micro-Telmetro, el Motógrafo, el Aerófono, la Pluma Eléctrica, etc. etc. y como si esto no bastara, ha venido por último, Mr. Edison y ha inventado el Fonógrafo.

El Fonógrafo sirve para conservar los sonidos, sean ó no comunes, ó articulados: de manera que no solo las reproduce una vez, sino que los reproduce cada vez que quiere uno poner en accion el aparato. Este guarda la palabra como una arca cualquier objeto, y no hay más que abrirla para encontrarlo.

Los experimentos hechos con el Fonógrafo en la Academia de Ciencias de París, en el Instituto Real de Lóndres y en presencia del prodigio, los sábios académicos no pudieron dominar su entusiasmo, y rompieron en aplausos atronadores.

En la gran Exposicion Internacional de París, la comision científica le dió una medalla de oro, como inventor más notable de la época.

De sus últimas invenciones, su Teléfono y Fonógrafo, pueden considerarse entre las más elevadas. Sus usos futuros y su importancia, no pueden ser apreciados actualmente.

Segun las últimas noticias recibidas del Sr. Edison, sabemos que ha logrado la solucion del gran problema; de aplicar la electricidad para producir la luz, y no un motor para la maquinaria más exterior.

Hasta ahora, los científicos más distinguidos solo han podido dividir la luz eléctrica en diez partes. El Sr. Edison ha descubierto la manera de dividirla en diez mil veces: tambien, propone utilizar el poder de las cataratas, cascadas, ríos, etc., que ahora se pierde, por medio de la electricidad; y no dice que por este medio, el poder de 100.000.000 de toneladas de agua que se precipitan del salto del Niágara cada hora, con una caida de 160 piés, se podrá trasmitir, por medio de la electricidad en todo el Estado de Nueva-York, para mover la maquinaria de sus innumerables fábricas. Cuando advertimos que este poder sería igual al vapor producido por 260.000.000 de toneladas de carbon, cuya suma es lo que se consume anualmente por el mundo entero, se podrá formar una idea de la inmensidad del proyecto.

Como ensayo de este gran descubrimiento, se trasmite en la actualidad por la electricidad, el poder suficiente de un pequeño rio en el Estado de Connecticut, para mover la maquinaria de la Fábrica de Walker, que emplea 200 hombres, y que dista del rio la cuarta parte de una milla, y se dice que en esta trasmision solo se pierde 20% del poder del rio.

Tengo el honor de presentar á vdes. primeramente el Fonógrafo. Este aparato reproduce la voz humana, el canto, los silbidos, y la música instrumental; la voz humana, sea cantando ó hablando, ó cualquier otro sonido; no solo lo repite por una sola vez, sino por todas cuantas veces se desee; ya sea ahora, ó dentro de un mes, un año ó un siglo; siempre lo mismo.

Este aparato tan sencillo, reproduce la voz humana por medio de la mecánica—resultado deseado por tanto tiempo, y lo que no han podido lograr miles de hombres de la más alta inteligencia, despues de muchos años de estudio.

Me propongo ahora demostrar prácticamente los trabajos de este aparato, siguiendo el programa, y empezaremos con el «Himno Nacional.»

(Se cantó el Himno Nacional y el Fonógrafo repitió el canto.)

Ahora tenemos grabado el glorioso himno nacional en una lámina delgada de estaño, como este. (El Dr. Wise presentó al público la lamina donde queda grabado el Himno Nacional, para verlo repetido *in eternam*, por el Fonógrafo) por medio de un disco cuya diafragma vibrante contiene un pequeño pezon puesto en movimiento por la vibracion de la voz, dando al mismo tiempo vuelta al cilindro para recibir la impresion de los sonidos cantados.

Para producir este himno nacional, palabra ó sonido cualquiera, no se requiere más, si no que el pezon vuelva á recorrer su mismo camino. El pezon, al pasar sobre las impresiones anteriormente cansadas por la voz, pone en vibracion otra vez el diafragma y de consiguiente reproduce el mismo sonido, como ustedes oirán:

(Volvió á repetirse el canto del Himno Nacional, sin variar en nada al primero.)

En seguida continuaremos con algunos experimentos prácticos.

(Se ejecutaron varios experimentos de canto, de palabra y de músics, etc., etc., todos satisfactorios.)

Como dije ántes, esta invencion está en su infancia ó en embrion.

Este aparato simplemente, ilustra un principio basado hace muchos años, y al fin encontrado por el Sr. Edison.

Imaginemos que se puede hablar por medio de esta pequeña lámina de estaño, mandándola en un sobre por el correo á un amigo, miles de leguas distante, quien podrá aplicándola en una máquina, oir á vivo voz lo que se le dice. Dentro de pocos años de la fecha, esto será lo general en todas partes.

Ayudará al esposo cuando tenga que viajar, á dejar sus instrucciones á su esposa. Ayudará á un enamorado para hablar á su amada sin verla, y ella podrá oir sus palabras de amor cuando lo desee.

Las más sublimes canciones ó melodías de la Peralta, ó de Adelina Patti, podrán mandarse como una carta á cualquier parte del mundo. No tiene fin los usos á que este simple aparato podrá aplicarse dentro de pocos años.

Tambien tengo el honor de presentarles el Teléfono del Sr. Edison.—Este instrumento hará desaparecer al Telégrafo como existe hoy, en pocos años. Y aun hoy mismo está en uso general en Nueva-York y otras grandes poblaciones, especialmente para los caminos de fierro, banqueros, comerciantes y etc., como comunicacion particular.

Hay varios Teléfonos construidos bajo diversos principios. El Teléfono de Bell, como el colocado entre Chapultepec y el Palacio Nacional depende de una magneta para conducir sonidos; mientras que yo pretendo que la invencion del Sr. Edison es enteramente original y depende únicamente en un disco de carbon, del tamaño de una peseta, que sirve para trasmitir la voz. Debo decir á vdes. que el descubrimiento del Sr. Edison de las propiedades y la sensibilidad del carbon, es una de las maravillas del siglo; casi todas las invenciones, como el Micrófono, dependen de esto. Con esta aparato, la voz ó sonido cualquiera, puede ser trasmitido á 20 ó 1.000 millas.

Este pequeño aparato es el Micrófono y Teléfono combinado. Hablando por conducto de esta boquilla, aunque sea de tres ó cuatro piés de distancia, se puede oir á 20 ó 40 millas, clara y distintamente todas las palabras que se digan.

Imaginaos que un padre haya colocado un pedazo de carbon en la sala en donde su hija tiene una entrevista con su amante. ¡Cuán sorprendidos no quedarán estos al saber que él, es su reconvenzo, está

10 14

al tanto de toda la conversacion entre los dos amantes por medio de un Micrófono.

¡Un pedazo de carbon, señores, es hoy el receptáculo del pensamiento universal!

Nuestro amigo Wise, terminó su discurso y á continuacion puso en prácticas su variedad de experimentos fonográficos, que dieron motivo para que la concurrencia colmara con atronadores aplausos, los primeros experimentos hechos en el país, con el invento sublime de este siglo, que es mecánico y ficticio será llamado el siglo de Edison.

Terminados los experimentos y puestas prácticas del Fonógrafo, el Sr. Wise, con esa amabilidad que lo caracteriza, invitó á los concurrentes á que ellos mismos examinaran é hicieran uso de los aparatos fonográficos, telefónicos y micrófonos. Unos pasaron en accion al Teléfono, otros al Micrófono y los más, profirieron al Fonógrafo, cuyo mecanismo es admirable por su sencillez y cuyo uso es fácil para todo el mundo.

Las varias mexicanas tuvo su ámina especial y algunos periodistas hicieron del Fonógrafo, para dedicar expresiones de admiracion hácia su autor. El jóven poeta Sr. Calvo, pronunció una elegante poesía dedicada á Edison y al Fonógrafo que fué recibida con aplauso de todos los concurrentes.

Quisiéramos comunicar á los lectores del Combate cuanto la pasado en la sesion del dia 10, pero sus columnas no lo permiten por hoy, reservándonos hacerlo en otra ocasion con la amplitud que merecen los inventos mas sorprendentes de un siglo ya rico y fecundo en invenciones.

Concluimos, pues, agradeciendo á nuestro compañero y amigo el Dr. Wise la gentil invitacion con que nos honró, para que pudiéramos observar y admirar los últimos inventos del Sr. Edison y saludando con entusiasmo el recuerdo del eminente inventor cuyo nombre es para nosotros tan grande en la ciencias y en la física, como Dupuytren en la medicina, Shakespeare, Voltaire y Rousseau en la literatura, como Cristóbal Colon en la navegacion, como Fulton en la locomocion, como Miguel Angel, Murillo, Velazquez, Claudio, Gallet y Cellini en el arte, laborioso como Palissy, constante como Colon, revolucionario como Morse, valeroso como Chenier, constante como Watt y sereno como Fulton, no retrocede, no desmaya ante las asechanzas y la befa de la ignorancia, sino que lucha y trabaja, revela y propaga la idea de unir el pensamiento y la palabra, el canto y la música en toda la extension de nuestro planeta. Los Lores de Inglaterra escudian sus sueños puros con una chispa eléctrica que veia de Madrid, hoy se recogerá la chispa, y la voz de toda la humanidad que llegará por el teléfono, se repetirá en el Micrófono y quedará grabada eternamente en la lámina fonográfica.

¡Los mundos se mueven por Colon!

¡Los espacios se sondearon por Kepler!

¡Galileo mandó moverse á la tierra, la iglesia la esclavizó, pero la tierra obedeció á Galileo!

¡Gutemberg nos legó la imprenta!

¡Franklin domió el rayo!

¡El pensamiento unió de humanidad por Morse!

Las distancias se extrecharon por Fulton!

¡Lebon dió luz á la humanidad!

¡Tomás A. Edison nos ha dado aparatos, á quienes ha dicho ¡¡¡Parlad!!!

El lápiz, el brazo y la electricidad declaron, y á la voz de su genio ¡están parlando ya! con su otro dón la humanidad que no reconoce fronteras ni leyes á la naturaleza y los secretos á ¡¡¡Dios!!!

J. G. Puncn.

The National Democrat.

HAIWAIN, N. A., NOVEMBER 7, 1878.

Ha! Ha! Ha! Ho! Ho! Oh-h-h! We would have to put one of Edison's phonographs to do justice to the occasion. The daily *Herradura* says we clip items from it. Why, those poor dear little soul—we have been watching for a chance to clip something ever since the day of our adopty, and have not yet found a single paragraph worth a clip—except a death notice one day. But it is quite remarkable that for a day or two after our paper is read the daily items will come a reeling, if not clipped, from our columns.

Chanity Entertainment.—The entertainment at the Opera House last Friday evening proved a success both as to attendance and performance. The programme was quite lengthy, but it had been arranged with a view to fill up the time in case the phonograph could not be present, which was not certain until within a few days of the time. The exercises opened with quite a brilliant piano solo by Miss Sadie Malloy, followed by a tableau of the "Pansies," consisting of nineteen pretty little girls tastefully dressed in white and grouped together. Then came a solo and chorus "Hide-a-Cot," conducted by Prof. Blacker, the "o being taken by his little nephew, who has a very pleasing voice with fine compass. Frank Elliott then gave a little address stating that the object of the entertainment was to raise money to relief a large family of colored people who have had to be helped by citizens, back to the South where they came from. Misses Lillie Hereford and Jennie Liggett then gave recitations which were well rendered and received with applause. Next was a piano solo by Miss May Frost well executed, followed by a tableau "Lt. Artist's Dream." Miss Jessie Glassbore then recited "Mamma Obliges" in excellent style. A humorous dialogue "The Wrong Man" was well performed by a number of young ladies and gentlemen.—Then followed a solo and quartet "The Little Ones at Home," followed by a tableau "Out in the Cold," a very effective representation of a poor little boy sing in the street with the snow fal[illegible] upon her while a song was sung in the d[illegible] by Miss Lillie Tepper with beautiful effe[illegible]. Next was a recitation by Jos. Kemper, [illegible] a duet quartet "The Swiss [illegible] Misses Clara, Wilson, Tepper, [illegible] Mooney, Perkins, Reed, Morse and [illegible] next a recitation by Miss Clara Ellis, and another double quartet "Uncle John." Miss Carrie Osborn then executed a very nice solo on the piano, followed by a tableau in three scenes "The Bridal"—first, bidding good bye to her father; second, renewal [illegible] bound; third, the wedding. Master Roy Avery, a little midget, then gave a recitation, and was repeatedly encored. Master Percy Glassford, another little one, also recited a piece, showing much talent for one so young. "Nancy Lee" was then sung as a solo and chorus, Jr. S. G. Perkins taking the solo. This was followed by a piano solo duet by Misses Jessie and Maggie Liggett. The next on the programme was a very amusing thing, called the "Pink Sisters," consisting of [illegible] dozen or more young ladies with high white hats ending in a shiny peak, black dresses, white handkerchiefs about the shoulders, and large pink bead fans, with which they brought on their mandies on the stage in Hutchinson Family style, singing "We're a band of sisters," a "Station" by one of the sisters and a song and chorus were the novelties presented.

The most interesting part of the entertainment to most of the audience was the exhibition of Edison's Phonograph by two of his assistants. The machine worked splendidly and demonstrated the wonderful invention to perfection, in all the different experiments of talking, laughing, coughing, whistling, etc. Mr. Perkins tipped a little of "Dolly Brown's Baby," and Miss Wilson sang "Auld Lee" which were repeated with precision, except when the gentleman who turns the crank gave a sudden jerk, when the tone would be considerably elevated; if the cylinder is turned very rapidly the tone will be sent up several octaves.

Much credit is due to Mr. and Mrs. Morrow, Mr. Jones and other teachers and scholars of the city, to Miss Palmer who arranged the "Misses" and others who assisted in the entertainment, all of whose names we are not possessed of.

We have received the following for publication in t[illegible] connection;

Haiwain, Nov. 6th, 1878.

Thomas A. Edison, Esq.,

Dear Sir:—I have been deputed by the school children, of this city, to get up the Charitable Entertainment at the Opera House on the 1st inst., to communicate to you their thanks for the loan of your phonograph on that occasion. The instrument was a source of great interest and gave universal satisfaction. Yours, very respectfully,

J. W. Bayard, Jr., Chairman.

N[illegible] William Cassaday, [illegible]

—I have been requested by the school children of this city, who got up the Charitable Entertainment at the Opera House on the 1st inst., to return to you their thanks for your valuable services on that occasion, [illegible]ibiting that unrefined instrument, the [illegible]ph. Yours, very respectfully,

W. Bayard, Chairman.

Receipts of the entertainment.....$81 00
Expenses,.....16 00

Balance,.....$64 50

H. G. McFarland, Treasurer.

EL FONOGRAFO.—Ayer tuvimos el gusto de hacer una nueva visita á este personaje, que no nos atrevemos á llamar mágnico, porque para ello nos la dado razones convincentes.

Parece que algunos dudaban sobre el invento, que otros creian que la expresión era una sofistiracion de la mágnica de Edison, sin faltar quien atribuyera á ventriloquismo ó prestidigitacion las maravillas de que ya hemos hablado.

La resion privada del *fonógrafo* se verificó en etiqueta ni aparato, en la casa número 14 del calleion de Santa Clara y esquina del Cisne de Mayo, casa de toda punto decorapada, que sin embargo se sujetaba á la mas escrupulosa inspeccion.

Entre las personas que recordamos como asistentes á la entrevista con el fonógrafo, mencionaremos á las siguientes:

Lics. Ignacio Mariscal, Joaquin Alcalde, Luis Mendez, Manuel G. Prieto, Sres. Mariano Barcena, Guzmeldo Mendoza, Pedro Santacilla, Francisco Urquidi, José Antonio Gamboa, *Lomelí* y algun otro que no tengo en este momento en la memoria.

El exámen, las esperiencias y que resultados fueron lerdísimos, probadísimos en ten distinguida reunion las entusiasmo sincero y apasionado, que equipaje á una orquesta espontánea y cepitódula al inmortalizador de la palabra humana.

El Sr. P. de Greea que estaba en la reunion propuso que cada uno de los circunstantes soltase una cinnta pulabrea al *fonógrafo*, lleiendo su nombre en seguida para reminiscs á Edison—el peruanito—fué acogido con entusiasmo, y uno á uno dijeron sus nombres al inventor.

Quisiéramos haber podido conservar en la memoria los pensamientos elevados y los rasgos de verdadera elocuencia que se confieron al fonógrafo.

La comision era interesilsima, no obstante notamos de un pequeño círculo de amigos, los palmados de siempre, á cada revelacion del invento singular, y como todos rodeaban el aparato y en tan reducido círculo, tan independiente de subdivisiones, la atencion tan patente, se disipó hasta la mas leve sombra de duda en la decreccion cuando se trató de entusiasmarse, con las finísimas puntos de contacto, que tienen las preciosísimas melindas al tratarse de las obras del génio.

Prometemos ocuparnos mas estension del fonógrafo, y nuestros lectores á todos los pormenores del progreso á que hagan no conocimiento con una de las *maravillas* mas *sorprendentes* del presente siglo.—*Guillermo Prieto.*

Libre Cambio, 22 de 1878.

EN TORNO DE LA VOZ DE EDISON.

No es fácil hacerse una idea de la sensacion que ha producido en todo el mundo el descubrimiento de Edison. Los periódicos de todas las naciones, los de todas las ciudades, los de todas las aldeas, no hablan de otra cosa. Los sabios, los literatos, los artistas, los hombres de negocios, las mujeres, los niños, todos, todos, todos, no hablan de otra cosa. Es el tema de todas las conversaciones, de todas las discusiones, de todas las disputas. Es el asunto de todos los artículos, de todos los folletines, de todas las novelas, de todas las poesías. Es el objeto de todas las miradas, de todas las preocupaciones, de todas las atenciones. Es el pensamiento de todas las cabezas, el sentimiento de todos los corazones, la palabra de todas las bocas.

Y no es para menos. Ese descubrimiento es el mas grande, el mas estupendo, el mas maravilloso, el mas sorprendente, el mas estraordinario, el mas portentoso, el mas prodigioso, el mas milagroso, el mas estupefaciente, el mas pasmoso, el mas asombroso, el mas admirable, el mas estupendo, el mas estraordinario, el mas estraordinario, el mas estraordinario

den 19. December 1878.

In Eßlingen den 17. Dec. fand Vierstellung des Gewerbevereins und der Bürgergesellschaft wurde hier gestern Abend das Wunderkind der neuesten Erfindungen, der Phonograph, einer äußerst zahlreichen Versammlung vorgeführt. Der Vortrag hatte sich in 2 Theile; ein mehr theoretischer, den Prof. Mach behandelte, verbreitete sich mit experimentaler Illustration über das Wesen und die Gesetze des Schalles und legte in die wissenschaftlichen Grundlage. D. Strenger, ein gebovener Amerikaner, bezeigt in Ludwigsburg, sei in Stuttgart bei Prakt. Techn hie günstigen von Hall, Heilbronn ꝛc. ihren vorausgegangenen Beifall auch hier geschmeichelt. In zum Theil, pfunkfeier Rede sagte er die Grundprinzipien des Instrumente und den Modus seiner Thätigkeit auseinander. Sehr interessant und ansprechend war die kurze Skizze über den praktischen Erfinder des Telephonen, den Amerikaner Edison. Die Brodem D. Sprengers waren überaschend. Ohne nur die in einer deutschen Sprache aufgesprochene Rede den Schall- oder Vibrationsfortgang entsprechend aufsprichet, sondern auch Nichtsprechendes, sofern es nur laut und hörbar ist, gesprich auch und sogar getreu wiedergibt z. B. Orchester, Gesänge, Pfeifen, ein gelungenes Lied. Die Erfindung liegt, das liegt wenn noch so unter Kinderlachen, aber es ist kein Zweifel, es ist einer großen Entwicklung

Übertragen am 19. Dec. 1878.

The Phonograph.—The phonograph is being exhibited daily in action at the various establishments of the London Stereoscopic Company, who are sole licensees of Mr. Edison's patent. As the nature of the point of the stylus is found to be important in affecting the articulation, these points are now made of ruby. Any improvements Mr. Edison makes on this, his favourite invention, will be reproduced by Mr. Senk, the maker in England. The Stereoscopic Company have also issued an interesting shilling pamphlet on the phonograph, including extracts from Mr. W. H. Preece's lecture before the Physical Society, and the reports and interviews of several American journalists with Mr. Edison.

7. Whether the unaided force of voice impinging upon the diaphragm, and proximity of the mouth to the diaphragm to effect a record?

These depend in a great measure upon the volume of sound delivered into the reproduction. If the reproduction is to be made audible to an audience, considerable force is requisite in the original utterance; if for the individual only, the ordinary (subdued). In both cases the original utterances are delivered directly in the mouth-piece of the instrument. An audible reproduction may, however, be had by speaking at the instrument from a distance of from two to three feet in a loud tone. The application of a conical tube or funnel to collect the sound waves, and the construction of an especially delicate diaphragm and embossing point, &c., are the simple means which suggest themselves to effect this. The writer has not as yet given this stage of practical difficulty in gathering up and retaining a vertical part of the sound waves diffused about the original source within a radius of, say, three feet (sufficiently removed not to be annoying to a speaker or singer).

THE PHONOGRAPH AND ITS FUTURE.

By T. A. EDISON. *

Of all the writers' inventions, none has commanded such prominent and earnest attention throughout the civilized world as has the phonograph. This fact he attributes largely to that peculiarity of the invention which brings its possibilities within range of the speculative imaginations of all thinking people, as well as to the almost universal applicability of the foundation principle, namely, the gathering up and retaining of sounds hitherto fugitive, and their reproduction at will.

From the very abundance of conjectural and prophetic opinions which have been disseminated by the press, the public is liable to become confused, and less accurately informed as to the immediate result and effects of the phonograph than if the invention had been one confined to certain specific application, and, therefore, of less interest to the masses. The writer has no fault to find with this condition of the discussion of the merits and possibilities of his invention: for, indeed, the possibilities are so illimitable, and the probabilities so numerous, that he—though subject to the influence of familiar contact—is himself in a somewhat chaotic condition of mind as to where to draw the dividing line. In point of fact, such line cannot with safety be defined in ordinary inventions at so early a stage of their development. In the case of an instrument of the nature and scope of the phonograph, it is practically impossible to indicate it to-day, for to-morrow a truth may extend it almost indefinitely.

There are, however, certain stages in the development process which have thus far been actually reached; certain others which are clearly within reach; and others which, though they are in the light of to-day to be classed as possibilities, may to-morrow become probable, and a little later actual achievements. It is the intention of the writer in this article to confine himself to the actual and the probable, to the end that a clearer conception of the immediate realization of the phonograph may be had. He contradicts to the public press and the world of science the imaginative work of pointing and commenting on the possible. It is in view of the liberal manner in which this has already been done, and the handsome treatment he has received at their hands, that he for the first time appears in print in discussion and comment upon the merits of one of his own inventions.

In order to furnish a basis upon which the reader may take his stand, and accept or combat the logic of the writer in his presentment of the possibilities of the phonograph, a few categorical questions are put, and answers given upon the essential features of the principle involved:

1. Is a vibrating plate or disc capable of receiving a complex motion which shall correctly represent the peculiar property of each and all the multifarious vocal and other sound-waves?

The telephone answers affirmatively.

2. Can such complex movement be transmitted from such plate by means of a single embossing point attached thereto, to effect a record upon a plastic material by indentation, with such fidelity as to give such indentations the same varied and complex forms; and, if so, will this embossing point, upon being passed over the record thus made, follow it with such fidelity as to retransmit to the disc the same variety of movement, and thus effect a restoration or reproduction of the vocal or other sound-waves, without loss of any property, essential to producing upon the ear the same sensation as if coming direct from the original source?

The answer to this may be summed up in a statement of the fact that by the application of power for uniformity of movement, and by attention to many seemingly unimportant and minor details, such as the form and material of the embossing point, the proper dampening of the plate, the character of the material embossed, the formation of the mouthpiece over the plate, &c., the writer has at various times during the past week reproduced the wares with such degree of fidelity in each and every detail as to astonish his assistants to read, without the loss of a word, one or more columns of a newspaper article unfamiliar to them, and which were spoken into the apparatus when they were not present. The only perceptible loss was found to be in the quality of the utterance—a non-essential in the practical application of the apparatus. Indeed, the articulation of some individuals has been very perceptibly improved by passage through the phonograph, the original utterance being mutilated by imperfection of lip and mouth formation, and these mutilations eliminated or corrected by the mechanism of the phonograph.

3. Can a record be removed from the apparatus upon which it was made, and replaced upon a second without mutilation or loss of effective power to vibrate the second plate?

This is a mere mechanical detail, presenting no greater obstacle than having proper regard for the perfect interchangeableness of the various working parts of the apparatus—not so nice a problem as the manufacture of an American watch.

4. What as to facility of placing and removing the record-sheet, and as to its transportation by mail?

But ten or fifteen seconds suffice for placing or removal. A special envelope will probably be required for the present, the weight and form of which, however, will but slightly increase the cost of postage.

5. What as to durability?

Repeated experiments have proved that the indentations possess wonderful enduring power, even when the reproduction has been effected by the comparatively rigid plate used for their production. It is proposed, however, to use a more flexible plate for reproducing, which, with a perfectly smooth stone point, dimmed or sapphire, will render the record capable of from 50 to 100 repetitions, enough for all practical purposes.

6. What as to duplication of a record and its permanence?

Many experiments have been made, with more or less success, in the effort to obtain electrotypes of a record. This work has been done by others, and though the writer has not as yet seen it, he is reliably informed that, very recently, it has been successfully accomplished. He can certainly see no great practical obstacle in the way. This, of course, permits

ARTICULATION.—We make the following quotation from an exhaustive and excellent paper on "Speaking Machines," in *Good Words* for July:—"Articulate sounds we all know can be separated into two elements, vowels and consonants, the former being the groundwork of the latter, or, as Max Müller remarks, 'consonants fall under the category of noises,' due to the working of the mechanism producing them. The pure vowels are produced by a con tinuous expiration, the mouth being kept open, but the size of its cavity varied by altering the position of the lips and palate. The vibration of the vocal chords yield as indiscriminate mixture of sounds—a compound tone; the mouth forms a resonant chamber, like a cave; and by adjusting the size of this chamber certain elements of the compound tone are strengthened to the exclusion of the rest; just as the sound of a Jew's harp, when held between the teeth, is intensified by the resonance of the mouth, and modified by the size we permit our tongue to give the cavity. These changes can be recognised if we pronounce successively *e* (as in he), *a* (as in hay), *o* (as in oh), *oo* (as in cool).

"The theory of vowel sounds was first enunciated by Wheatstone, and confirmed by the experiments of Donders, whilst the classical researches of Helmholtz, leave but little doubt as to the origin of these sounds. Helmholtz, in fact, has not only dissected the vowel sounds, and discovered their constituent elementary tones, but he has put together these elementary tones yielded by different tuning forks, and so built up the entire series of vowels by mechanical means.

"Certain consonants, as *b*, *t*, *d*, *v*, &c., may also be produced by continuous currents of air, modified by the tongue and lips. Other consonants, such as *m* and *n*, or *b* and *p*, &c., can only be produced by momentarily stopping the current of air, and commencing or finishing the vowels by a kind of explosion, thus, *ba*, *at*, *ne*, &c.

"It is possible to make a rough imitation of the larynx by simply rolling a sheet of *indiarub* into a narrow tube, and over one end, tying side by side, a couple of strips of thin india-rubber; on blowing through the tube a musical note is obtained, which can be varied in pitch by squeezing the tube, and so altering the tension of the india-rubber vocal cords. Nay, more, when speech has been lost by disease or removal of the natural vocal chords, artificial ones, formed of a vibrating tongue, or' reed' of metal or ivory, have been made, and inserted in the larynx of the sufferer, restoring to him at once the power of speech. In fact, so successful is this artificial substitute, that the only difference noticeable, appears to be the peculiar monotone of the speaker; who, however, has the advantage of having a variety of voices at command, for by selecting a grave 'reed,' to-day, he can roar like Bottom, the weaver, and by using a high pitch to-morrow, speak with the shrillness of a shrew."

Tel Journ Octobr 15 78
Del Jne Sept 15. 78

THE *Scientific American* for August 24, gives a detailed description with drawings of a simple and inexpensive phonograph which can be made by amateurs. It consists of a straight rod or square of wood run with two parallel V grooves along its face; and a mouthpiece with diaphragm, and spring point, constructed to glide along the rod by means of guides cut in the frame of the mouthpiece in such a position that the probe is over the grooves. A strip of tinfoil is smoothly lapped over the rod and held by bent cards. On moving the mouthpiece by hand along the rod and speaking into it the record is taken, and can be similarly reproduced.

Tel. Journ July 15 78
Del Journ Aug 15. 78

THE PHONOGRAPH.—It is said that Edison has improved the phonograph so that if spoken to at a distance of 15 feet it will intelligibly reproduce the speech. This increased sensitiveness is largely due to steel bearings having been supplied to the cylinder, so as to give it unvarying uniformity of motion.

LATIN is said to be the language which gives the best results with the phonograph.

SCIENCE may be elevated to a whistle by turning the phonograph recording it fast enough, and the whistle may be recorded by a second phonograph, revolving slower, so as to give out the original sound.

Tel Journ Apr 1. 78

THE PHONOGRAPH AND VOWEL SOUNDS.

It has been pointed out by Professor Fleeming Jenkin, and Mr. J. A. Ewing, in a letter to *Nature*, that whereas rotating the barrel of the talking phonograph at different speeds gives corresponding differences of pitch in the sounds, it does not alter their quality. This result appears to disagree with Helmholtz's theory that the characteristic quality of each vowel is given by the predominance of a constituent note of definite pitch in the sounds uttered. For the absolute pitches of the constituents of the vowel sounds in the experiments in question were all altered in the same proportion, so th.. the absolute pitches of the predominant notes varied greatly: yet the vowel quality was unchanged. Another fact has been elicited in these experiments, namely, that if a scale be sung into the phonograph with one vowel sound, such as O, the wave-form of the marks on the tinfoil does not remain unchanged at all pitches.

Del Jne May 1. 78

At the Crystal Palace on Good Friday the phonograph made its *début* before a miscellaneous audience. The instrument exhibited was made by Mr. Stroh, the well-known mechanician. The cylinder is driven by regulated clockwork instead of by hand, and the heavy fly-wheel necessary to give uniform motion in turning by hand is therefore discarded. A considerable number of people, including members of the newspaper press, assembled in the Open House to hear the wonderful "talking machine"—as it is not very happily named, Mr. J. P. Edwards, of the Postal Telegraph Service, courteously undertook to explain the action of the instrument, and to superintend the giving of a variety of instructive illustrations of its powers. Instrumental Music, songs, duets (recorded by means of a double mouth-piece), talking, and many other sounds, both odd and common, were faithfully rendered to the amusement and surprise of the audience. We understand that the Stroh Company intend to continue the public exhibition of the phonograph at the Palace, and elsewhere throughout the country. Phonographs can be obtained from them at prices ranging from five to thirty guineas.

EDISON'S Patent, No. 2927, dated July 31, 1877, of which we give an abstract in the present number, serves to illustrate how an invention is generally evolved. In this patent, Edison describes a means of recording ordinary Morse signals by the indentations of a style on a sheet of paper enveloping a cylinder or plate with a V shaped spiral groove cut in its surface. The indented record so obtained was afterwards to be utilised, if required, in sending the same message automatically by means of the indentations. In this contrivance we have, to all appearance, the groundwork of the phonograph. The inventor's mind was prepared by it to receive the suggestion, which would germinate into a recorder and reproducer of actual sounds. This priceless seed is said to have been sown by accidents. While experimenting one day with a telephone, a style attached to the diaphragm, when it was vibrating under the voice, pierced Edison's finger and drew blood. We suppose the idea of the phonograph at once flashed upon him, for he saw that there was force enough in the style to record speech by indentations on a yielding substance, as in his preconceived telegraph apparatus. If this interpretation be correct, we may also draw the moral from it that no original idea is utterly worthless, and no good work is ever thrown away: for, at least, it may in time become the root of something better. Edison's indenting telegraph may never be practically applied, but it has borne wonderful fruit in the phonograph.

It is stated that the Edison Phonograph was suggested in 1865 by an Italian mechanic of the Val d'Aosta (Signor Manetti), and published in the *Divitia* of Rome for July 10, 1865, and in the *Petit Journal* of Paris, for November 22, 1865.

Paris
Journ
the p
given

In my opinion this would be the only advanta of the proposed unit, an advantage of too sm importance to compensate the serious incon niences which its adoption would present fro other points of view. With the *volt*, the *weber*, t *ohm*, and the *farad*, we possess a complete syste of absolute electrical units, based on the cen metre-gramme-second. We are, furthermore, acce tomed to regard as derived units the multiples whi represent a million of the fundamental units, as the submultiples which represent the one-million part of such units; and we designate these deriv units by the special denominations formed by pr fixing "mega" or "micro" to the name of t fundamental unit. Either the fundamental unit, one or other of its derivatives is used, according which is best adapted to the electrical magnitude dealt with in telegraphy. Thus the *volt* is almo exclusively used to express differences of potenti the *megavolt* being so large and the *microvolt* small that it is very rarely these derived units e be made to represent differences of potential simple figures. The *megohm*, on the contrary, almost as often employed as the *ohm*, all resistanc of dielectrics being such more simple to express the *microhm* has only a thin than the *ohm*, while the *microhm* has only a thin vertical value. The *megohm* accords with the *farad* where the fundamental unit is so large a quantit that the *microfarad* is the only one of its derivative which corresponds to the quantities used in tel graphy. The whole capacity of a transatlan the insulated conductor, such as the cable, presents end of a piece of which springs, which presses against a small piece of india-rubber tubing fixed to the centre of the diaphragm. The piece of rubber acts as a cushion, and greatly improves the action of the apparatus, as it is found that if the stylus is attached directly to the diaphragm the action is not satisfactory. The diaphragm moves and the recording the impressions on the foil (lead) on the

EDISON'S PHONOGRAPH.

[1922.]—A VERY interesting experiment (in which the writer participated) was tried on Dec. 26th with Mr. Edison's phonograph. It was the transmission of the mechanical talking over a circuit, by the Edison Telephone Company, by means of telephones. The matter to be transmitted was deposited up on the phonograph, and during the repro duction of the same the telephone was held in front of it. A number of people at the other end heard it perfectly. JOHN TYNDALL.

ARTICULATION.—We make the following quotation from an exhaustive and excellent paper on "Speaking Machines," in *Good Words for July*:—"Articulate sounds we all know can be separated into two elements, vowels and consonants, the former being the groundwork of the latter, or, as Max Müller remarks, 'consonants fall under the category of noises,' due to the working of the mechanism producing them. The pure vowels are produced by a continuous expiration, the mouth being kept open, but the size of its cavity varied by altering the position of the lips and palate. The vibration of the vocal chords yield an indiscriminate mixture of sounds—a compound tone; the mouth forms a resonant chamber, like a cave; and by adjusting the size of this chamber certain elements of the compound tone are strengthened to the exclusion of the rest; just as the sound of a Jew's harp, when held between the teeth, is intensified by the resonance of the mouth, and modified by the size we permit our tongue to give the cavity. These changes can be recognized if we pronounce successively *e* (as in *he*), *a* (as in *hay*), *o* (as in *oh*), *oo* (as in *cool*).

"The theory of vowel sounds was first enunciated by Wheatstone, and confirmed by the experiments of Donders, whilst the classical researches of Helmholtz, leave but little doubt as to the origin of these sounds. Helmholtz, in fact, has not only dissected the vowel sounds, and discovered their constituent elementary tones, but he has put together these elementary tones yielded by different tuning forks, and so built up the entire series of vowels by mechanical means.

"Certain consonants, as *k*, *t*, *r*, &c., may also be produced by continuous currents of air, modified by the tongue and lips. Other consonants, such as *m* and *n*, or *b* and *p*, &c., can only be produced by momentarily stopping the current of air, and commencing or finishing the vowels by a kind of explosion, thus, *ba*, *ap*, *ma*, &c.

"It is possible to make a rough imitation of the larynx by simply cutting a sheet of foolscap into a narrow tube, and over one end, lying side by side, a couple of strips of thin india-rubber; on blowing through the tube a musical note is obtained, which can be varied in pitch by squeezing the tube, and so altering the tension of the india-rubber vocal cords. Nay, more, when speech has been lost by disease or removal of the natural vocal chords, artificial ones, formed of a vibrating tongue, or 'reed' of metal or ivory, have been made, and inserted in the larynx of the sufferer, restoring to him at once the power of speech. In fact, so successful is this artificial substitute, that the only difference noticeable, appears to be the peculiar monotone of the speaker; who, however, has the advantage of having a variety of voices at command, for by selecting a grave 'reed,' to-day, he can roar like Bottom, the weaver, and by using a high-pitch to-morrow, speak with the shrillness of a shrew."

THE *Scientific American* for August 24, gives a detailed description with drawings of a simple and inexpensive phonograph which can be made by amateurs. It consists of a straight rod or square of wood ran with two parallel V grooves along its face; and a mouthpiece with diaphragm, and spring point, constructed to glide along the rod by means of guides cut in the frame of the mouthpiece in such a position that the points lie over the grooves. A strip of tinfoil is smoothly lapped over the rod and held by beer-wax. On moving the mouthpiece by hand along the rod and speaking into it the record is taken, and can be similarly reproduced.

THE PHONOGRAPH.—It is said that Edison has improved the phonograph so that if spoken to at a distance of 13 feet it will intelligibly reproduce the speech. This increased sensitiveness is largely due to steel bearings having been supplied to the cylinder, so as to give it unvarying uniformity of motion.

LATIN is said to be the language which gives the best results with the phonograph.

SPEECH may be elevated to a whistle by turning the phonograph recording it fast enough, and the whistle may be recorded by a second phonograph, revolving slower, so as to give out the original sound.

THE PHONOGRAPH AND VOWEL SOUNDS.

IT has been pointed out by Professor Fleeming Jenkin, and Mr. J. A. Ewing, in a letter to *Nature*, that whereas rotating the barrel of the talking phonograph at different speeds gives corresponding differences of pitch in the sounds, it does not alter their quality. This result appears to disagree with Helmholtz's theory that the characteristic quality of each vowel is given by the predominance of a consistuent note of definite pitch in the sounds uttered. For the absolute pitches of the constituents of the vowel sounds in the experiments in question were all altered in the same proportion, so that the absolute pitches of the predominant notes varied greatly; yet the vowel quality was unchanged. Another fact has been elicited in these experiments, namely, that if a scale be sung into the phonograph with one vowel sound, such as O, the wave-form of the marks on the tinfoil does not remain unchanged at all pitches.

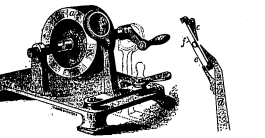
At the Crystal Palace on Good Friday the phonograph made its *début* before a miscellaneous audience. The instrument exhibited was made by Mr. Stroh, the well-known mechanician. The cylinder is driven by regulated clockwork instead of by hand, and the heavy fly-wheel necessary to give uniform motion in turning by hand is therefore discarded. A considerable number of people, including members of the newspaper press, assembled in the Opera House to hear the wonderful "talking machine"—as it is not very happily named. Mr. J. P. Edwards, of the Postal Telegraph Service, courteously undertook to explain the action of the instrument, and to superintend the giving of a variety of instructive illustrations of its powers. Instrumental music, songs, duets (recorded by means of a double mouth-piece), talking, and many other sounds, both odd and common, were faithfully rendered to the amusement and surprise of the audience. We understand that the Stereoscopic Company intend to continue the public exhibition of the phonograph at the Palace, and elsewhere throughout the country. Phonographs can be obtained from them at prices ranging from five to thirty guineas.

EDISON'S Patent, No. 2937, dated July 31, 1877, of which we give an abstract in the present number, serves to illustrate how an invention is generally evolved. In this patent, Edison describes a means of recording ordinary Morse signals by the indentations of a style on a sheet of paper enveloping a cylinder or plate with a V shaped spiral groove cut in its surface. The indented record so obtained was afterwards to be utilised, if required, in sending the same message automatically by means of the indentations. In this connivance we have, to all appearance, the groundwork of the phonograph. The inventor's mind was prepared by it to receive the suggestion, which would germinate into a recorder and reproducer of actual sounds. This fruitless seed is said to have been sown by accidents. While experimenting on the use of the telephone, a style attached to the diaphragm, when it was vibrating under the voice, pierced Edison's finger and drew blood. We suppose the idea of the phonograph at once flashed upon him, for he saw that there was force enough in the style to record speech by indentations on a yielding substance, as in his preconceived telegraph apparatus. If this interpretation be correct, we may also draw the moral from it that no original idea is utterly worthless, and no good work is ever thrown away: for, at least, it may in time become the root of something better. Edison's indenting telegraph may never be practically applied, but it has borne wonderful fruit in the phonograph.

IT is stated that the Edison Phonograph was suggested in 1865 by an Italian mechanic of the Val d'Aosta (Signor Mananti), and published in the *Diritto* of Rome for July 10, 1865, and in the *Petit Journal* of Paris, for November 22, 1865.

EDISON'S PHONOGRAPH.

FIGS. 1 and 2, for which we are indebted to the *Journal of the Franklin Institute*, Philadelphia, show the phonograph as at present constructed. Fig. 1 gives a general view of the instrument. Fig. 2



shows the diaphragm and stylus. The former is formed of a ferrotype plate, such as is employed in the ordinary telephone. The stylus is fixed to the end of a piece of watch spring, which presses against a small piece of india-rubber tubing fixed to the centre of the diaphragm. The piece of rubber acts as a cushion, and greatly improves the action of the apparatus, as it is found that if the stylus is attached directly to the diaphragm the action is not satisfactory. The diaphragm answers both for recording the impressions on the foil (lead) on the drum, and for reproducing the sounds, when the handle is turned. The diaphragm is mounted in a metal frame, attached to a moveable lever, which enables the point of the stylus to be withdrawn from the surface of the foil when the drum is to be screwed back to its starting position, after the impressions have been recorded. The dotted lines in fig. 1 show the position taken up by the frame and lever when the latter is turned back.

EDISON'S PHONOGRAPH.

[1878.]—A VERY interesting experiment, (in which the writer participated) was tried on Dec. 20th with Mr. Edison's phonograph. It was the transmission of the mechanical talking over a circuit, by means of wire. The circuit was worked by Edison's telephone. The matter to be transmitted was first stored up on the instrument, and during the reproduction of the sound the telephone was held in front of it. A number of people at the other end heard it perfectly. [illegible]

A WONDERFUL INVENTION.—SPEECH CAPABLE OF INDEFINITE REPETITION FROM AUTOMATIC RECORDS.

It has been said that Science is never sensational; that it is intellectual not emotional; but certainly nothing that can be conceived would be more likely to create the profoundest of sensations, to arouse the liveliest of human emotions, than once more to hear the familiar voices of the dead. Let Science now announces that this is possible, and can be done. That the voices of those who departed before the invention of the wonderful apparatuses described in the letter given below are for ever stilled is too obvious a truth; but whoever has spoken or whoever may speak into the mouthpiece of the phonograph, and whose words are recorded by it, has the assurance that the sounds may be reproduced audibly in his own tones long after he himself has turned to dust. The possibility is simply startling. A strip of indented paper travels through a little machine, the sounds of the air are vanquished, and our great grandchildren or posterity centuries hence hear us as plainly as if we were present. Speech has become, as it were, immortal.

The possibilities of the future are not much more wonderful than those of the present. The orator in Boston speaks, the indented strip of paper is the tangible result; but this travels under a second machine which may connect with the telephone. Not only is the speaker heard *now* in San Francisco for example, but by passing the strip again under the reproducer he may be heard tomorrow, or next year, or a next century. His speech in the first instance is recorded and transmitted simultaneously, and indefinite repetition is possible.

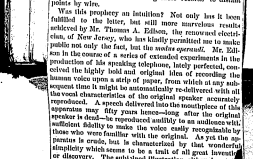
The new invention is purely mechanical—no electricity is involved. It is a simple affair of vibrating plates, thrown into vibration by the human voice. It is crude yet, but the principle has been found, and modifications and improvements are only a matter of time. So also are its possibilities other than those already noted. Will letter writing be a prevailing art of the past? Why not, if by simply talking into a mouthpiece our speech is recorded on paper, and our correspondent can by the same paper hear us speak. Are we to have a new kind of books? There is no reason why recitations of our modern Ciceros should not be recorded and indefinitely bound as they can be run the indented slips through the machine, and in the quiet of our own apartments listen again, and as often as we will, to the eloquent words. Nor are we restricted to spoken words. Music may be crystallized as well. Imagine an opera or an oratorio, sung by the greatest living vocalists, thus recorded, and capable of being repeated as we desire.

The invention, the credit of which is due to Mr. Thomas A. Edison, should not be confounded with the one referred to by us in a previous number, and mentioned in our correspondent's letter. That device is illustrated on another page of this issue, and is of much more complicated construction. Mr. Edison has sent us sketches of several modifications and different arrangements of his invention. These we shall probably publish in a future number.

To the Editor of the Scientific American:

In your Journal of November 3, page 273, you made the announcement that Dr. Rosapelly and Professor Marey have succeeded in graphically recording the movements of the lips, of the veil of the palate, and the vibrations of the larynx, and you prophesy that these, among other important results, may lead possibly to the application of electricity for the purpose of transferring these records to distant points by wire.

Was this prophecy an intuition? Not only has it been fulfilled to the letter, but still more marvelous results achieved by Mr. Thomas A. Edison, the renowned electrician, of New Jersey, who has lately permitted me to make public not only the fact, but the *modus operandi*. Mr. Edison has in the course of a series of extended experiments in the production of his speaking telephone, lately perfected, conceived the highly bold and original idea of recording the human voice upon a strip of paper, from which at any subsequent time it might be automatically re-delivered with all the vocal characteristics of the original speaker accurately reproduced. A speech delivered into the mouthpiece of this apparatus may fifty years hence—long after the original speaker is dead—be reproduced audibly to an audience with sufficient fidelity to make the voice easily recognizable by those who were familiar with the original. As yet the apparatus is crude, but is characterized by that wonderful simplicity which seems to be a trait of all great inventions or discovery. The subjoined illustration, although not a



actual design of the apparatus as used by Mr. Edison, will better serve to illustrate and make clear the principle upon which he is operating.

A is a speaking tube provided with a mouthpiece, O—[X is a metallic diaphragm which responds powerfully to the vibrations of the voice. In the center of the diaphragm is secured a small chisel-shaped point. D is a drum revolved by clockwork, and serves to carry forward a continuous fillet of paper, having throughout its length and exactly in the center a raised V-shaped boss, such as would be made by passing a fillet of paper through a Morse register with the lever constantly depressed. The chisel point attached to the diaphragm rests upon the sharp edge of the raised boss. If now the paper be drawn rapidly along, all the movements of the diaphragm will be recorded by the indentation of the chisel point into the skeleton boss—i.e., having no support underneath, is very easily indented; to do this, little or no power is required to operate the chisel. The tones of small amplitude will be recorded by slight indentations, and those of full amplitude by deep ones. This fillet of paper then receives a record of the vocal vibrations or air waves from the movement of the diaphragm; and if it can be made to contribute the same motion to a second diaphragm, we shall not only see that we have a record of the words, but shall have them re-spoken; and if that second diaphragm be that of the transmitter of a speaking telephone, we shall have the still more marvelous performance of having them re-spoken and *transmitted by wire at the same time to a distant point.*

The reproducer is very similar to the indenting apparatus, except that a more delicate diaphragm is used. The reproducer, B, has attached to its diaphragm a thread which in turn is attached to a hair spring, H, upon the end of which is a V-shaped point resting upon the indentations of the boss. The passage of the indented boss underneath this point causes it to rise and fall with precision, thus contributing to the diaphragm the motion of the original one, and thereby rendering the words again audible. Of course Mr. Edison, at this stage of the invention, finds some difficulty in reproducing the finer articulations, but he quite justified by results obtained, from his first crude efforts, in his prediction that he will have the apparatus in practical operation within a year. He has already applied the principle of his speaking telephone, thereby causing an electro-magnet to operate the indenting diaphragm, and will undoubtedly be able to transmit a speech, made upon the floor of the Senate, from Washington to New York, record the same in New York automatically, and by means of speaking telephones redeliver it in the editorial *sanctum* of every newspaper in New York. In view of the practical inventions already contributed by Mr. Edison, is there any one who is prepared to gainsay this prediction? I for one am satisfied it will be fulfilled, and that, too, at an early date.

EDWARD H. JOHNSON, Electrician.

(22593.)—Phonograph.—I do not think that the writing of either the phonautograph or the phonograph would be made larger by increasing the size of the diaphragm beyond certain limits because, as I understand, the sound waves which act on the latter do not exist also be increased, and often in a greater proportion. 2. The principle of the phonautograph and of the phonograph are the same, in so far as they both register sound vibrations. The character of the latter are, however, engraved upon the cylinder surface. A phonautograph could be so constructed as to be used as a phonograph. 3. A phonograph might be made to speak by drawing a straight slide covered with tinfoil under the point, but a cylinder is infinitely more compact and convenient.—BURDALT. *P. S.*

Le phonographe. — A peine sommes-nous revenus de la surprise que nous a causée la découverte du téléphone, qu'un nouvel appareil, peut-être plus merveilleux encore, s'impose à notre admiration. Le phonographe, en effet, ne se contente pas de transporter à une distance quelconque tous les sons qui l'ont impressionné, mais encore il les enregistre, les fixe et peut les répéter ainsi souvent qu'on le désire. Déjà M. Nimrod Bridgest, dans son intéressante communication à la Société des Ingénieurs civils, s'est consultre le principe sur lequel est appareil est basé. Mais, depuis, des simplifications y ont été apportées, et aujourd'hui le phonographe, comme le téléphone lui-même, nous étonne peut-être encore plus par sa simplicité que par les résultats qu'on en obtient.

M. Thomas A. Edison vient en effet de construire un

phonographe d'une simplicité telle qu'il semble impossible de le simplifier encore.

Une membrane vibrante, semblable à celle d'un téléphone, est armée en son centre d'une pointe métallique très-fine qui vient s'appuyer sur une mince feuille d'étain enroulée sur un cylindre. Ce cylindre peut être animé simultanément d'un mouvement de rotation et d'un mouvement de translation suivant son axe, ce qu'on obtient facilement en filetant l'axe qui le porte, et en remplaçant l'un des coussinets par un écrou. De cette manière, la pointe décrit sur la bande d'étain une hélice ayant le même pas que la vis de l'axe du cylindre. Quand la membrane entre en vibration, la pointe agissant sur l'étain y grave une série de points, plus ou moins profonds et plus ou moins espacés, suivant l'intensité et la rapidité des vibrations qu'elle exécute. C'est là pour ainsi dire une sténographie complète, et parfaite, de tous les sons qui ont provoqué les mouvements de cette membrane.

Pour reproduire les sons, une deuxième membrane, armée comme la première d'une pointe métallique, est mise en rapport avec le cylindre dont nous venons de parler, et un ressort délicat force cette pointe à rester constamment en contact avec la feuille d'étain. En conséquence la seconde membrane devra reproduire les sons reçus par la première et cela un aussi grand nombre de fois qu'on le voudra, et aussi longtemps qu'il sera possible de conserver la feuille d'étain sans altération.

Il faut bien entendre que la vitesse du cylindre reste toujours la même, sinon les vibrations devenant plus ou moins rapides, le son émis changerait de nature, une voix la basse pourrait, par exemple, si le mouvement du cylindre s'accélérait, devenir une voix de fausset ou inversement.

Nous ne chercherons pas ici à prévoir toutes les applications possibles de ce nouvel appareil, lorsqu'il aura reçu les perfectionnements qui en rendront l'usage facile et permettront d'amplifier les sons qu'il émet de manière à lui donner une intensité égale ou même supérieure à celle de ceux qu'il a enregistrés : c'est une besogne que nous laisserons à l'imagination de nos lecteurs, car il est difficile de toucher ce sujet sans paraître entrer dans le domaine du rêve et de l'utopie. L'avenir seul pourra nous faire connaître l'étendue des services que peuvent nous rendre ces merveilleux appareils.

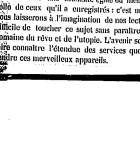
PHYSICAL SOCIETY.—March 2nd, 1878.

Professor W. G. ADAMS, President, in the chair.

THE following candidates were elected members of the society:—Messrs. J. P. Kirkman and Dr. W. J. Russell, F.R.S.

Mr. SIDNEY TAYLOR exhibited the colours produced in thin films by sonorous vibrations. A piece of thin brass was polished with a triangular, circular, or rectangular aperture, and bearing a thin film of soap solution, was placed horizontally on one end of a long, shaped tube; the beam of the electric lamp, after reflection from it, was received on a screen. It was shown that when a sound is emitted in the neighbourhood of the open end of the tube, as it is taken by a whistle the note which is indicated by the different colours of the reflected light, and each note has its own peculiar colour figure; and further, with different instruments we have different figures. When a violin bow was the sound employed, a figure of two lobes on a nodus was produced, which was exhibited by changing the note, and with a whistle the successive changes traversed by two lines at right angles were observed.

Mr. W. H. Preece exhibited and described the phonograph. After referring to the manner in which the preceding communication bore on the subject of the telephone, he went on to explain the construction of the two instruments exhibited, which have been made in accordance with the published accounts of the apparatus, and details received from the inventor, Mr. T. A. Edison, by Mr. Pidgeon and Mr. Stroh respectively. In the first of these the receiving and recording cones are distinct, the former being of ferrotype iron, and the latter of paper, whereas in the second form of apparatus, both these functions are performed by one and the same flattened cone of paper. They also differ in that, in Mr. Pidgeon's apparatus, the drum receives its motion by hand, and in that of Mr. Stroh a descending weight is caused to communicate motion by a suitable train of wheels, which motion can be controlled and regulated by an adjustable pair of vanes. In both cases the drum is of



brass, turned over by a spiral groove, and the whole is mounted on a screw of the same pitch. The manner of using the phonograph is extremely simple. The drum having been covered with the foil, a uniform movement of rotation is given to it, and a fine metal point, firmly fixed in the centre of the receiving plate is brought in contact with it, care being taken to place the point accurately over the groove. It was this plate be sung or spoken to, the tinfoil will be indented in accordance with the vibrations communicated to the metal point. The emitting plate having been provided with a retainer, its point is now brought into contact with the indented foil, the point of the receiving plate, and the drum caused to revolve at the same velocity, fairly, and the sounds are given out. It will be seen that Mr. Stroh's apparatus has an advantage over that of Mr. Pidgeon in that it secures a constant rate of rotation; but, on the other hand, the sounds emitted by the paper drum appear to be more distinct than those from the iron. A number of experiments were performed with the instruments. The sounds were reproduced at times with remarkable distinctness, and when Mr. Spagnoletti and Mr. Sedley Taylor sang "God Save the Queen," as a duet, through a double mouthpiece, the two voices could be clearly distinguished as its being reproduced. It was shown that even when an indented sheet of tinfoil has been employed to emit sounds, it retains its form with such perfectness, that the sounds can be reproduced by means of it a second and even a third time with nearly equal distinctness.

Prof. GRAHAM BELL pointed out that the articulation of the instruments was very similar to what he had observed in the earlier forms of telephone, and he had no doubt, judging from his own experience with that instrument, that the phonograph will ere long be so adjusted as to articulate much more perfectly. He anticipated that the quality of the sound would be found to vary as the rate of rotation was altered, as well as the pitch, and this proved on experiment to be the case.

Edison's Acrophone.

In our last issue we gave an illustration of Edison's Phonograph, taken from the patent issued to him, as it appears in the *Official Gazette* of February 19th, 1878. We have since examined the machine in operation in the *Tribune* building, where it is attracting a good deal of attention, and the cut we gave of it is substantially correct. What is the practical value of the phonograph?

Mr. Edison himself is not now prepared to answer this question. He says: "All the phonographs that have as yet been exhibited are imperfect, or rather very meagre in their results; they have been mere experiments." He has, however, as he states, made application for a patent for a talking-machine, or acrophone, which, when placed in a locomotive, will raise its voice and announce in giant tones, that can be heard for miles: "I am Engine Marmsduke, and will stop at Boonton Station," or, when placed on ship-board, lighthouses, or on dangerous rocks, sound out a warning to be heard over miles off.

This suggests something really valuable, and Edison is evidently the man to work it out. The phonograph, then, is at present, a mere curiosity, and certainly it is one which has required for its production the utmost sort of genius, and patience. Mr. Edison will please hurry up the acrophone. Many anxious voyagers upon the great deep, enveloped in dismal fog, will gratefully welcome the new fog horn.

Speaking of Edison's phonograph, the New York *Herald* remarks that "the Americans are the most inventive people in the world, and besides a multitude of minor inventions of more or less utility they have contributed more than their share to those greater conquests of man over nature which entrench all the other intellectual achievements of our time. Even in the early beginnings of our history, at a time when our population had not reached two millions, Franklin's discoveries in electricity gave him a pre-eminence in that fruitful branch of science which will never be eclipsed. When he announced his capital discovery of the identity of lightning and electricity the Royal Society laughed at his theory, but the laughers were soon subdued by the cogency of his experiments, and the Royal Society in 1753 made amends by conferring on him, unsolicited, its highest honor, the Copley medal. It was then an American who set in motion the train of discoveries whose most important practical result is the electric telegraph. It was our Morse who made the final success and established the first telegraph. It was our Fulton that made the first successful application of steam to navigation. Our Draper preceded Daguerre in making sun pictures, although the Frenchman got almost all of him in turning the discovery to use. That most beneficent discovery of the age, the use of anæsthetics in medicine and surgery, is of American origin. All the things on which we have now touched, as well as the latest invention of Edison, deserve a place in the highest ranks of successful physical research. Of inventions which consist in purely mechanical applications of well known principles Americans have distanced all competition in multitude, in variety, and in importance. A catalogue even of the most useful and noteworthy would be tiresome by its length. To say nothing of Whitney's cotton gin and other early inventions, enough has been done in the lifetime of persons still young to confer for lustre on American ingenuity. The sewing machine, the mowing and reaping machines, the machines for planting seeds and threshing grain, are a few among the many which are as the leaves of the forest for multitude. With our dwelling on achievements which have gone into history we may safely challenge all Europe to show an inventive genius who deserves to stand by the side of Edison."

Helmholtz's Vowel Theory and the Phonograph

THE results obtained by Messrs. Jenkin and Ewing in their experiments with the phonograph, described in NATURE, vol. xvii. p. 382, are so different from those reached in some experiments recently performed by Mr. Clarence J. Blake, of this city, and in connection with myself, that I venture to call attention to the fact.

With the design of solving the question of change of quality in vowel tones by reproducing the rate of rotation of the phonograph cylinder, we performed a number of experiments, of which I mention a few as briefly as possible.

1. The vowel *a* and *e* were spoken into the mouth-piece of the instrument, each four times in succession, while the cylinder was rotated at the rate of one revolution per second, as timed by the beats of a clock-pendulum. On rotating the disc so as to reproduce the vowel-sounds, there were by system, *aa*, *e*, each repeated four times, when the rate of rotation was one revolution per second, but on increasing the velocity to two revolutions per second, but the first sounds were indistinct, while the last gave the second. The first sounds were indistinct, while the last gave the vowel *e* very clearly. At half revolution per second, *ee*, *aa*, were distinctly heard.

2. The vowel *a* was sung while the cylinder rotated at different rates of speed. On reproducing the sounds, the cylinder being revolved more slowly than at first, the vowel *aa* was heard, changing to *ô*, *o*, *ŏ* falling to *a* again as the velocity was slackened a little.

3. The vowel *a* was spoken while the cylinder made one revolution per second. On reproducing the sound, the rate being half a revolution per second, *aa* was heard, changing to *a* when the rate increased to one revolution, and at three revolutions per second *i* was heard.

4. The vowel *a* was spoken several times in succession, the rate of the cylinder being gradually accelerated. On reproducing the sound by a uniform and slow rotation, *aa* and *ai* were heard; on rotating faster, *ê* and *i*.

Several other experiments were tried in the short time during which the instrument was at our service, all of which were strikingly confirmatory of Helmholtz's theory. Difficulty was experienced in reproducing the highest vowels *i*, *ê*, probably on account of want of resilience of response in the disc. The ball of a reed-pipe was placed over the mouth-piece of the instrument when the sound was to be reproduced, for which a piece of pasteboard was substituted in some of the trials.

We believe that no other these experiments were rigorously quantitative, as the phonograph promises to be a valuable aid to research in the future. Very probably others may have worked with the same end in view, and if so it would be interesting to learn what has been their experience. CHAS. R. CROSS

Boston, U.S., April 29

The Phonograph

SINCE writing our former letter on the phonograph (NATURE, vol. xvii. p. 382) I have had the advantage of seeing some of the work that Prof. Fleeming Jenkin is doing with his own instrument, which was most kindly sent down to the city that I examined. This work convinces me that the phonograph has already risen above the level of a mere illustration and plaything, and I have suggested this paper to the Royal Society of Edinburgh, should it be considered worthy of publication, as I think it will be by the point of the phonographic suggested conclusions. Some of these original tracings I had the pleasure of seeing yesterday, and they are full of interest. I have termed them "speech curves." They differ considerably from the phonautographic speech-curves of Leon Scott and Koenig, which only succeeded with the vowels, and from the logographic speech-curves of Mr. Barlow, which only succeeded with the consonants, in so much as they succeed with both. In such a word as *bab*, for example, uttered rather than sung, but not simply spoken, as the vowel would otherwise be not last long enough for subsequent study, we have first the "explosive" beginning, which the curve gradually, but irregularly, rises, then the "attack," where there is generally a bold serrated projection, with numerous rather sudden valleys; next the "glide" where there is a perfect, tumult of curvatures arising from the passage of voice through a continually changing resonance chamber, producing a rapidly and continuously changing but intricate series of vowel sounds, which gradually settle down into the "vowel" proper. In the vowel, if well intoned, the curve remains constant for a considerable number of periods, beautifully reproducing itself, but, as the intoner becomes exhausted, "vanishing" more gradually to silence, the distinctive peculiarities of the curve disappearing one by one, till a dead level is again reached. . . . .

Then Prof. Fleeming Jenkin suggests that these curve to "analysis," reducing it to the exquisite "simple" curves of which it can be composed. This corresponds to determining the "partial" tones (*partialtöne*, *theiltöne* of Helmholtz, on which all but the lowest are called *Ubertonreihe*, *oberthellton*, or *combination thones*, whence the unfortunate English word *overtone*, which is constantly confused with *partials*, thus assuming a part for the whole) out of which the whole "compound" tone is formed. The first two partials are much stronger than the rest. The second often stronger than the first (hence the frequent confusion of octave), the others generally very weak, although exceptionally one of the higher partials may be stronger. As many as five partials, as far as I remember, were traced out in the analysis. Prof. Jenkin showed me, which he had just received from Edinburgh, the results differ materially for different speakers, but that it is peculiarity in the "phase" with which the different partials enter into combination. Helmholtz showed that this difference of phase would materially alter the form of the curve, but would not alter the appreciation of quality by the ear depending upon the actual partials and their degrees of loudness alone.

The phonograph, as I have said, re-makes rather a worse "prise" than a "proof" of the human voice. This seems, of course, that the delicate upper partials, on which all the accuracy depends, are shaken. In some respects this is advantageous for the very elaborate inquiry which Prof. Fleeming Jenkin has in-stituted, for it enables him to catch the bold outlines on which genius depend, without being at first bewildered by the delicate details which make specific differences. Our speech sounds are, of course, individual, and what is recognised as the same speech sound varies in the same speaker within the limits of its genus, almost every time it is said. We shall do much if we establish the genus. The extent of Prof. Jenkin's researches, as he contemplates them, and the error with which

his initial experiments, tracings, and analyses have been conducted, lead us to hope that we have at least got an instrument which will enable us to solve the elementary problems of phonetics that have hitherto almost baffled us, although it is not united, as yet, to fix the results of its delicate work which save my own special object of investigation.

April 30 ALEXANDER J. ELLIS

On repeating the experiments with the phonograph mentioned by Mr. A. J. Ellis in NATURE, vol. xvii. p. 382, we have a different result to record from that of Mr. Ellis. Experience to differ in several respects from his. Doubtless each instrument possesses its own individual characteristics; hence it will be the more needful to exercise caution with respect to generalizations, until the following instruments are few and in the hands of few observers. Mr. Ellis has been careful to say that the failure of the instrument in which his results were obtained, and the same of Mr. Stroh is a guarantee for the correctness of the mechanism. The phonograph which I have been working is of homelier make, and not provided with a driving-train or governor, but simply turned by hand. The same disc—a three-inch foreatype plate—serves as receiver and transmitter of the sounds. The latter I have been, if anything, a little too thin for the purpose.

On trying the sounds *aahoo*, *aadoo*, &c., I found the consonants perfectly distinguishable, except the sibilants, *hoo*, which is similar to Mr. Ellis's *fu*, and *doo*, which is replaced by the intermediate, *voo* (perhaps *thoo*), and could be distinguished from *aadoo*. Neither the consonants *g* and *k* were ever heard *and* and *ant*; but *hoogoo*, with the soft *g*, was rendered clear by the instrument as *hôôd*. My phonograph makes the same two possible difference between the words *hoo* and *hôo* when carefully spoken, the diphthongal sounds coming out beautifully as *hôoôd* and *hôoôt*. On reversing the motion of the handle, *hôoôd* and *hôoôt* were unintelligible. The double nature of some of our consonantal letters is very clearly demonstrated by this process of reversal of motion, as Messrs. Fleeming Jenkin and Ewing have already shown. To the sounds they name let me add that of *sh* in the word *chapoo*, which we ordinarily pronounce *tshoo*. This word gives a very perfect result when uttered in the machine.

The greatest difficulty—that of getting an instrument to acknowledge the sibilants—is a difficulty that all who have worked with phonographs, phonautographs, or stethoscopes, admit. The remedy mentioned by Prof. Moyer, that of using a mouthpiece with a very small hole, has the inconvenience of diminishing materially the loudness of the articulation of the machine. I have found it better to fasten a strip of tin or matching across the opening, edgeways, so that the sound impinges on the edge of the strip. With this device sibilants are reproduced; the word *scissors* becomes practicable, though "Sarah" is still impossible. One of Dr. Stroh's instruments, which was shown at the Crystal Palace during Easter week, gave *s* and *z* fairly. In a shuffle (hence the *ea* are not much altered) *Steady, boys, steady*, is given with less marked

THE PHONOGRAPH AND ITS FUTURE.

By THOMAS A. EDISON.

Or all the writer's inventions, none has commanded such profound and earnest attention throughout the civilized world as has the phonograph. This fact he attributes largely to the wide scope of its practicability, and to its beneficial influence within range of the speculative imaginations of all thinking minds. It would also appear that the universal applicability of the population principle, namely, the gathering up and retaining of useful knowledge, is peculiarly met by the production of the phonograph.

From the very abundance of conjectural and prophetic opinions which have been advanced, and are continually by the press, the public is liable to become confused, and hence necessarily inclined not to consider the practical uses and effects of the phonograph thus if the invention had been accomplished without specific applications, and therefore of comparative interest to the masses. The writer has no fault to find with this condition of the discussion of the subject, and possibilities of his invention; for, indeed, the possibilities are in fact unlimited, the practicability so assured as to be entirely subject to the influence of familiar contact—is himself in a somewhat chaotic condition of mind as to where to arrange his thoughts like. In point of fact, such has current with safety in favor of development. In the case of an invention of the nature and scope of the phonograph, it is practically impossible to indicate it to-day, for to-morrow a trifle may extend it almost indefinitely.

There are, however, certain stages in the developing process which have thus far been perfected; certain others which are clearly within reach; and others which, though they are in the light of to-day discovered as possibilities, may to-morrow become probable, and a little later actual achievements. It is the intention of the writer in this article to confine himself to the actual and the probable, and to curtail a clearer conception of the immediate realization of the phonograph may be had. He conceives to the public the best view and the most accurate, the imaginative work of speculating and commenting upon the possible. It is in this line of development in which the has already been in those, and the most favorable treatment he has received at their hands, that he for the time being proposes to confine himself to discussing and comment upon the merits of one of his own inventions.

In order to furnish a basis upon which the reader may take his stand, and accept or combat the ideas of the writer in his present advocacy of the practicability of the phonograph, a few categorical questions are put and answered, given upon the essential features of the principle involved:

1. Is a vibrating plate or disk capable of receiving a complex motion which shall correctly represent the peculiar property of each and all the undulations of vocal and other sound-waves?

The telephone answers affirmatively.

2. Can such complex movement be transmitted from such plate, by means of a single embossing-point attached thereto, to effect a record upon a plastic material by indentation with such fidelity as to give to such indentations the same varied and complex form; and, if so, will this embossing-point, upon being passed over the record thus made, follow it with such fidelity as to reirreunit to the disk the same variety of movement, and thus effect a restoration or reproduction of the vocal or other sound-waves, without loss of any property essential to producing upon the ear the same sensation as if coming direct from the original source?

The answer to this may be summed up in a statement of the fact that, by the application of proper *modifications* of the movement, and by attention to many seemingly unimportant and minor details, such as the *form* and material of the embossing-point, the proper *steepening* of the plate, the character of the material embossed, the formation of the mouth-piece over the plate, etc., the writer has at various times obtained the spoken into the apparatus when they were put upon it. The only perceptible loss was found to be in the quality of the reproduced sounds, and this was traceable to application of the apparatus. Indeed, the modification of some individuals has been very perceptibly improved in passage through the phonograph, the subjective utterances being mutilated by imperfection of lip and mouth formation, and these mutilations eliminated or corrected by the mechanism of the phonograph.

3. Can a record be removed from the apparatus upon which it was made, and replaced upon a second without mutilation or loss of effective power to vibrate the sound-plate?

This is a more mechanical detail, presenting no greater obstacle than having proper regard for the perfect interchangeableness of the various working parts of the apparatus—but no nice a problem as the manufacture of the American watch.

4. What as to facility of placing and removing the record-sheet, and as to its transportation by mail?

But ten or fifteen seconds suffice for such placing or removal. A special cardboard will probably be required for the present, the weight and form of which, however, will not slightly increase the cost of postage.

5. What as to durability?

Repeated experiments have proved that the indentations possess wonderful enduring power, even when the reproducer has been effected by the comparatively rigid plate used for their production. It is proposed, however, to use a more flexible plate for reproducing, which, with a perfectly smooth steam polish—diamond or sapphire—will render the record capable of from 50 to 100 repetitions, enough for all practical purposes.

6. What as to duplication of a record and its permanence?

Many experiments have been made, with more or less success. In the effort to obtain electrotypes of a record. This work has been done by others, and, though the writer has not as yet seen it, he is reliably informed that, very recently, it has been successfully accomplished. He can certainly see no great practical obstacle in the way. This, of course, permits of an indefinite multiplication of a record, and to the preservation for all time.

7. What are the requisite force of wave impinging upon the diaphragm and the proximity of the mouth to the diaphragm to effect a record?

These depend in a great measure upon the volume of sound desired in the reproduction. If the reproduction is to be made audible to an audience, considerable force is requisite in the original utterance; if for the individual ear, only the ordinary conversational tone (even a whisper has been reproduced). In both cases the original utterances are delivered directly in the mouth-piece of the instrument. An audible reproduction may, however, be had by speaking at the instrument from a distance of from two to three feet in a loud tone. The application of a fueling tube or funnel to collect the sound-waves and the construction of an especially delicate diaphragm and embossing-point, etc., are the simple means which suggest themselves to effect this. The writer has not as yet attempted the use of the duplex sound-tube attention, but sees no practical difficulty in gathering up and bringing a sectional part of the sound-waves diffused about the original source, within a radius of, say, three feet (sufficiently convenient for the user) and causing to a speaker or a listener.

The foregoing presentment of the stage of development of the phonograph is reached by the several essential features of the phonograph demonstrates the following *ex facto* principles:

1. The capacity of all manner of sound-waves heretofore relegated as "fugitive," and their permanent retention.

2. Their reproduction with all their original characteristics as will, without the presence or consent of the original source, and after the lapse of any period of time.

3. The transmission of such captive sounds through the ordinary channels of commercial intercourse and trade in material form, for purposes of communication or as merchantable goods.

4. Indefinite multiplication and preservation of such speech, sounds or music, without regard to the existence or non-existence of the original source.

5. The capitalization of sounds, with or without the knowledge or consent of the source of their origin.

The foregoing are the primary or base properties of the phonograph to the various branches of commercial and social life industry generally indicated will require the exercise of more or less mechanical ingenuity. Conceding that the approximate is practically perfect in so far as the faithful reproduction of sound is concerned, many of the following applications will be made the moment the new field of opportunities, which the writer is now about completing, is thrown open to the public. Others, though conceived as practicable, may be closely trench upon other applications which will immediately follow, but it is impossible to separate these because they are all enumerated under the head of probabilities, and require specific consideration. Among the most important may be mentioned: Letter-writing and other forms of dictating, books, education, reader, music, family records and the phonographic typographic applications as books, musical boxes, toys clocks advertising and signalling apparatus, speaking-etc., etc.

Letter-writing.—The apparatus now being perfected in mechanical details will be the standard phonograph, and may be used for all purposes except such as require special form of matrix, such as toys, clocks, etc., for an indefinite repetition of the same thing. The main utility of the phonograph is, however, being for the purpose of letter-writing or other correspondence, and in this it is made with a view to its utility for dictating purposes.

The general principles of construction are a flat plate or disk, with a spiral groove on the face, operated by clock-work underneath the plate; the grooves are cut very closely together, so as to give a great total length to each inch of surface—close calculation gives as the capacity of each sheet of foil, upon which the record is made, a the subscription of 40,000 words. The sheets being but ten inches square, the cost is so trifling that but 100 words might be put upon a single sheet economically. Still, it is problematical whether a such number of grooves per inch might not be the better plan—it certainly would for letters—but it is desirable to have but one class of machine throughout the world; and as very extended communications, if put upon one sheet, could be transmitted more economically than upon two, it is important that each sheet be given as great capacity as possible. The writer has not yet decided this point, but will experiment with a view of ascertaining the best mean capacity.

The practical application of this form of phonograph for correspondence is very simple. A sheet of foil is placed in the phonograph, the clock-work set in motion, and the mutter then stated into the mouth-piece without other effort than that which is dictation to a stenographer. It is then removed, placed in a light envelope, and mailed to the party addressed, ordinary channels to the correspondent, for whom reproduction. The phonograph letters may be dictated at home, or in the office of a friend, the *presence* of a stenographer not being required. The dictation may be as hasty or deliberate as best to forward or the flow utter them. The recipient may listen to his letter at his leisure, and may have it read in words per minute, and at the same time have himself read the matter, interjections, explanations, emphasis of inflections, etc., may be thrown into such letters, and all *fixed*.

In the early days of the phonograph, ere it has become universally adopted, a correspondent in Hong-Kong may possibly not be supplied with an apparatus, thus necessitating a written letter of the old-fashioned sort. In that case the writer would use his phonograph simply as a dictating-machine, his clerk writing it out from the phonograph at leisure, causing as many words to be uttered at one time as his memory was capable of retaining until he had written them down. This clerk need not be a stenographer, nor need he have been present when the letter was dictated, etc.

The advantages of such an innovation upon the present slow, tedious, and costly methods are too numerous, and too readily suggest themselves, to warrant their enumeration, while there are no disadvantages which will not disappear coincident with the general introduction of the new method.

Dictation.—All kinds and manner of dictation which will permit of the application of the mouth of the speaker to the mouth-piece of the phonograph may be as readily effected by the phonograph as in the case of letters. If the matter is for future reference, he would much prefer in acting it up in type, to use his ears in lieu of his eyes. He has tried and found it useful. It would be even worth while to compel witnesses in court to speak directly into the phonograph, and thereby obtain a more unimpeachable record of their testimony.

The increased delicacy of the phonograph, which is in the near future, will enlarge this field rapidly. It may then include all the sayings of not only the witness, but the judge and the counsel. At all times also comprehend the utterances of public speakers.

Books.—Books may be read by the author's dictated preferential reader, or by such readers especially employed for the purpose, and the record thus made placed upon the shelves of the libraries, hospitals, the sick-chamber, or even with great profit and pleasure reached by the lady or gentleman whose eyes and hands may be otherwise employed; or, again, because of the greater enjoyment to be had from a book when read by an elocutionist than when read by the average reader. The ordinary record-book, containing the words from fifty to a hundred times as it will, would command a price that would pay the original reader well for the slightly increased difficulty in reading it aloud in the phonograph.

Educational Purposes.—As an elocutionary teacher, or as a literary teacher for instance, it will eventually be indispensable. By it difficult passages may be correctly rendered for the pupil ten, one, often score which he has only to apply to the phonograph for instruction. The child may thus learn to spell, commit to memory, a lesson or the like, etc., etc.

Music.—The phonograph will undoubtedly be liberally devoted to music. A *song sung* on the phonograph is rendered with marvelous accuracy and power. Thus a friend may sit in a concert hall and sing to a song which shall delight an evening company, etc. As a musical teacher it will be used to enable a pupil to master a new air, the child to form its first songs, or to sing him to sleep.

Family Records.—For the purposes of preserving the sayings, the voices, and *the last words* of the dying member of the family—as, for instance, a mother—the phonograph will unquestionably outrank the photograph. In the field of multiplication of voices and music, and the labor-saving invention of one and the same thing, the successful electrotyping of the original record is no exception. As this is a special step of publicity, it properly ranks among the probabilities. It cannot be long, after the invention, before a phonograph of the phonograph in this direction is in the production of

Phonographic Books.—A book of 40,000 words upon a single metal plate ten inches square thus becomes a strong probability. Duplicates, stereotypes, and privately these printed are too readily seen to need mention. Such books would be found to be of interest none are now in use. They would preserve more than the mental emanations of the brain of the author; and, as to books for the blind even, they would be unequaled. For the preservation of languages they would be invaluable.

Musical Boxes, Toys, etc.—The only element not absolutely necessary in the use of the phonograph is that which is already in the way of a perfect reproduction of sound. The fine finish of the plate, the high speed, the single sets of qualities, and even that is not totally lacking, and will doubtless be wholly absent in the reproducer. It should not, the musical box, or cabinet, of the present will be found equal to such a task with only the voice and the words of the human organism.

Toys.—A doll which may speak, sing, cry, or laugh may be safely promised as one of the first of the Christmas delights to be had from the phonograph. A cabinet of animal toy-and-so locomotives which may be supplied with material and set to work by sounds.

Clocks.—The phonographic clock will tell you the hour of the day, call you to lunch, send your lover home at ten, etc.

Advertising, etc.—This class of phonographic work is so plain to the foregoing that it is only necessary to call attention to it.

Speech and other Utterances.—It will be worth he proved the time to come when conversations the videos well as the telephone is in use—spoken phonograph letters will be the words of our Washingtons, Lincolns, Gladstones, etc., etc., and our children will be given as their "greatest store, etc., etc., and our children will be given as their "greatest store, etc., etc., and our children will be given as their "greatest store

defect of speech than if uttered *to Hendy, Leach, Alcock*. Another point of interest that has not, I think, been yet mentioned by observers is, that the marks corresponding to the vowel sounds differ when the sounds is at different distances from the vibrating plate, but that yet there is no difference in the sound of the vowel subsequently emitted by the machine; a result which confirms the previously known independence of the vowel sound of the phase of its component partials. For some time I thought my phonograph guilty of dropping its *h*'s [though not aside within the sound of *how hah*], but when that letter is spoken rapidly in a word it is recorded faithfully. *Happy land* is well heard in the instrument; and *How do you do?* is also registered. Curiously enough, this record is spoken almost as well backwards as forwards (except the *you*), and, especially if spoken to the machine with a strong Scotch accent. It is remarkable how useless an instrument without a checkwork regulator is for reproducing even the simplest of speech they are simply lost in noise. Altogether the study of speech by the phonograph is most interesting, and will furnish scope for valuable data to students of language and of elocution. It is impossible to make its performance without a tribute of admiration to the extreme ingenuity and skill of its inventor, Mr. Edison.

SILVANUS P. THOMPSON

University College, Bristol, May 1

the correspondent, if he is present, *to hear it while it is being recorded*. Thus we have a more perfect record of the action, but a complete and durable record of these words as the result of that action. The economy of time to society go further than to annihilate time and space, and hand up for posterity the mere utterance of man, without any other effort on his part than to speak the words?

In order to make this adaptation, it is only requisite that the phonograph shall be made slightly more sensitive to sound, and the telephone very slightly more sensitive to the beating force of the receiver, and it is accomplished. In the "Gower-Bell Telephone," invented and patented by the phonograph; as in its constantly improving use, it is found to cause a more decided vibration of the plate of the receiver. In this addition to the telephone may be looked for confidence with the other practical applications of the phonograph, and with almost equal certainty.

The telegraph company of the future—and that no distant one—will be simply an organization having a large system of wires, central and semi-central stations, managed by skilled attendants, whose sole duty it will be to keep wires in proper repair, and to give, by switch or shunt arrangement, prompt attention to a subscriber No. 921 in New York, when he signals his desire to have private communication with subscriber No. 1001 in Boston, for three minutes. The minor and totally inconsequential details which seem to arise as obstacles in the eyes of the present-traveling telegraph-man wedded to existing methods will wholly disappear before that remorseless Juggernaut—the needs of mankind—for will not the necessities of man summon rifles to compel to reap the full benefit of an invention which practically brings him face to face with whom he will, and, better still, doing the work of a conscientious and infallible scribe.—*North American Review*.

POWER FOR ELECTRIC ILLUMINATION.

THE electric light being simply the conversion into heat and light of the energy due to chemical action in a battery or of the energy derived from the consumption of fuel, and electric machine, the question which presents itself for consideration at the outset in contemplating the introduction of this mode of illumination is the cost of the necessary power. That the magneto-electric machine possesses numerous advantages over the battery in point of economy and efficiency needs no demonstration at this time, and it is to the employment of that apparatus to which we have reference. According to late investigations by M. Tresca, 1,000 burners supplied with a current from a Gramme machine required 7 horse power or 1 horse power per 100 burners; when, however, a less powerful apparatus was used, requiring but a little gas light, the expenditure was 15 horse power. So that, like all other commodities, the electric light is cheap at wholesale and dear at retail. Generally, however, it appears that 100 burners require 1 horse power, and for calculating the cost of the latter the direct expense of the fuel is reached. To this, however, must be added cost of machinery, interest on capital, maintenance, wages, etc. For an approximate idea of the relative outlay we again have recourse to Prof. Tresca's investigations. M. Jamin, in his recently published work, states that the electricity as a means of illumination is 75 per cent. cheaper than candles. M. Jamin, on the other hand, calls attention to published statements, wherein it is proved that the electric light is 62 per cent. dearer than gas. This assertion appearing in the *Annales des usines à gaz*, the explanation represent probably the extreme views of the advocates and opponents of the general introduction of electric illumination. M. Jamin adds, however, that the Lontin Company in Paris are now offering to rent magneto-electric machines and all apparatus for producing the light at a cost of 10 centimes per hour per hundred burners, the number of the latter for a period of ten to extend over certain contracted periods. The lights furnished to the Louvre by the Denayrouse-Bachhoff Company, according to the same authority, far surpass gas lights in brilliancy, and an economy of about 30 per cent. is effected.

In the above cases power is furnished by consumption of fuel. There are many instances, however, where natural sources of power may be utilized, and it is to these more especially that we desire here to draw attention. Whether it will ever be practicable to employ the rise and fall of the tides in New York Bay or the currents in the rivers to actuate motors which in turn shall drive magneto-electric machines is at least an open question. The destruction of the rocks at Hell Gate has for one result the augmenting of the force of the current at that point, and it would seem possible that some arrangement of water wheels could be contrived whereby this power might be utilized and a part of it used for supplying electricity for purposes of illumination. The same might be done on a small scale elsewhere. With a machine such as the Lontin, which is capable of giving a commercial divided current, or by the use of the simple Jablochkoff candle, where the entire paraphernalia of the electric lamp is abolished altogether, it would appear that the matter of lighting up a village or town by electricity has become an easy matter. A small water wheel, or even windmill, might furnish the power at little cost, and the remaining expenditures for maintenance would manifestly be small.

THE RADIOMETER AND THE SPHEROIDAL STATE.

THE following lucid exposition of the latest theories explaining the action of Crookes's radiometer, and the cause of the phenomenon known as the spheroidal state, was given by Professor Barrett in a recent address at the London Institution. He said: "To Mr. Stoney is unquestionably due the great honor of having been the first to try to explain the true theory of the radiometer." It was in the course of these investigations that Mr. Stoney has been recently led to show that the force which is so active in the high exhaustion that is necessary for the effective rotation of the radiometer is also present at ordinary atmospheric tension. Now, it is this force which forms the new explanation of the spheroidal state. In order to understand the calculation that occurs it must be recollected that, according to calculation, the number of molecules of air that at ordinary pressure occupy the space of a pin's head is 1,000,000,000,000,000; when the radiometer globe is exhausted of these molecules of air as far as we can do it by mechanical means, there are still some few millions remaining, and these are in constant motion. Heat makes them move more rapidly, cold more slowly. If we have two surfaces placed very near each other, one surface hot and the other cold,

THE PHONOGRAPH WINS A VICTORY.

The phonograph has been distinguishing itself lately in this city by its remarkably accurate reproductions of the correct notes of Mr. Levy, the famous performer on that instrument. Mr. Levy possesses the phenomenal ability of getting notes out of the cornet, which, he says, "are not there," or in other words, he plays airs in notes an octave lower than any one else has succeeded in producing on the cornet, and thus he has extended the range of his instrument over four full octaves. The phonograph, however, not only follows Levy, but surpasses him, by reproducing correct notes in entirely new octaves of its own origination, proving itself to have a compass of extraordinary range, if not especial tunefulness and brilliancy.

At a very pleasant reception given to Mr. Edison recently, in this city, a most interesting contest between Levy and the phonograph occurred. Messes. Edison and Johnson ably seconded the phonograph, and of course none but Levy could scientifically manipulate the cornet. Fresh tin foil being adjusted on the cylinder, the bell of the cornet was placed near the mouth piece, and "Yankee Doodle," first plain, and then garnished with variations of the most decorative character, assumed the form of dots on the foil. Without the loss of a note, the phonograph repeated it, and not only this, but even the peculiar expression imparted by the player, and the triumphant kind of a flourish which brought the tune to a conclusion, were reproduced with wonderful accuracy. A few several other popular airs had been similarly rephrased. Mr. Edison showed the effect of turning the cylinder at different degrees of speed, and then the phonograph proceeded utterly to rout Levy by playing his tunes in pitches and octaves of astonishing variety. It was interesting to observe the total indifference of the phonograph to the pitch of the note it began upon with regard to the pitch of the note with which it was to end. Gravely singing the tune correctly for half a dozen notes, it would suddenly soar into regions too painfully high for the cornet even by any chance to follow it. Then it delivered the variations on Yankee Doodle with a celerity that no human fingering of the cornet could rival, interspersing new notes, which it seemed probable were neither on the cornet nor on any other instrument—for instance. Finally the phonograph recited "Hagen on the Rhine" after its inventor, then repeated the poem with a whistling accompaniment, then in conjunction with two songs and a speech, all this on one tin foil, though by this time the remarks began to get mixed. Just here Levy returned to the charge, and played his cornet fiercely upon the much indented scrip. But the phonograph was equal to any attempts to take unfair advantage of it, and it repeated its songs, and whistles, and speeches, with the cornet music heard so clearly over all, that its victory was unanimously conceded, and amid hilarious crowing from the triumphant cylinder the cornet was ignominiously shut up in its box.

The occasion of Mr. Edison's reception was the exhibition of a fine organ made by Mr. Hilborne L. Roosevelt, of this city, for the Episcopal church in Rome, Italy. Some one, a reckless partisan of the phonograph, who was affected with enthusiasm over the victory of the instrument, and also by the fumes of the carbonic acid from a vicious beverage of French extraction, suggested that the phonograph be pitted against the grand organ. It was with difficulty that Mr. Edison, who, during the evening had repeatedly manifested a desire to do this, could be persuaded into confining himself to the simple exhibition that graph was thus saved the strain of a second struggle, with a more formidable competitor.

MR. THOMAS A. EDISON.

Many of our readers will recognize in the engraving the face of Mr. Thomas A. Edison, and others, who are not familiar with his appearance, may form a good idea of how the great inventor looks. Every one is acquainted with his telephone, phonograph, and other remarkable inventions, therefore we shall not notice them here.

Mr. Edison is above the medium height, and although he is only thirty-one years old, his iron gray hair and thoughtful eyes show the effects of continued study. He is genial, liberal, and entirely unostentatious. His mind, day and night, is on his projects; and even while eating his thoughts dwell on his inventions. His table conversation consists of occasional ejaculations regarding some new point in whatever project he may have in hand. He is at home in his laboratory, which is very large and complete in all of its appointments. He has a number of assistants, who are competent and quick to carry out his wishes, and they are often engaged on several widely different subjects at the same time. The experimental apparatus which is completed during the day is often tried at night when all is quiet and no visitors are present.

Notwithstanding his great mental labor, he avers that his health is good, and that as his occupation is pleasurable it does not tire him.

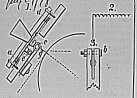
His residence and laboratory at Menlo Park are beautifully situated upon the brow of a hill that overlooks a picturesque valley. The beautiful landscape and the mountain air—Nature's best restoratives for the brain-weary—he has without the seeking.

Mr. Edison may well pride himself as to his position in the world of science, standing, as he does, first among the inventors of the day; and having, by his own energy and persistence, secured an income that enables him to carry forward on a grand scale such experiments as his prolific mind may suggest.

We publish in another column a detailed account of Mr. Edison's researches in telephony.

THE PHONOGRAPH AND ITS INVENTOR, MR. THOMAS A. EDISON.

(28) F. M., writes: "The parts of my phonograph are made as follows: The hollow brass cone is 3 c. cig. inches, with ¼ inch steel spindle 16 inches long, cooling at any brass foundry about $0.50 [illegible] inch twenty threads to an inch on spindle, and many on cones, but not on any. See Fig. 1. One of the



supports of spindle is sawed apart and drawn together by a bolt, A, causing the thread inside to cut its own way (not in the journal, as shown in Fig. 1. The base upon which the whole rests is 1 foot square and 3 inches thick, to give more hold to the spindle and stability to the whole. The disk, c (see Fig. 1), is made of beech, or other close grain wood, and is clamped between flesh (or rings, of which are 2 inches in diameter. This disk must be turned true from time to time on account of its getting warped by the moisture of the voice. It gives much better results than the more scholastic form-tips. A very essential part is the proper dampening of disk by pieces of rubber tubing and round rubber of the same material. It is also of great importance to have the needle chisel-shaped, and set at an angle of 45° in the hexagonal the cone. The smallest dancing needle is the best working. The reproducing funnel is 14 feet long and 3 inches wide at the top and ¼ inch at the bottom. It improves the working of the hole for speaking in top 2d is small, and also the paper between disk and top 2d is not in contain very much air.

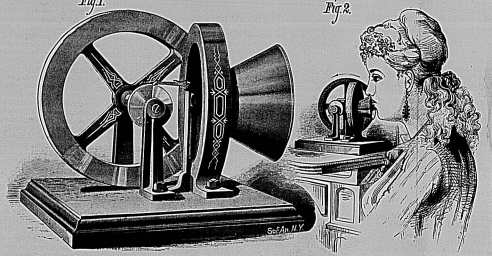
EDISON'S PHONOMOTER.

It is admitted that there is power in the human voice, but hitherto this power has been applied indirectly to produce mechanical results.

Mr. Edison in his telephone and phonograph experiments discovered that the vibrations of the vocal cords were capable of producing considerable dynamic effect. Acting on this hint he began experiments on a phonometer, or instrument for measuring the mechanical force of sound waves produced by the human voice. In the course of these experiments he constructed the machine shown in the engraving, which exhibits the dynamic force of the voice.

Fig. 1.

Fig. 2.



EDISON'S PHONOMOTER.

The machine has a diaphragm and mouth piece similar to a phonograph. A spring which is secured to the bed piece rests on a piece of rubber tubing placed against the diaphragm. This spring carries a pawl that acts on a ratchet or roughened wheel on the fly wheel shaft. A sound made in the mouth piece creates vibrations in the diaphragm which are sufficient to propel the fly wheel with considerable velocity. It requires a surprising amount of pressure on the fly wheel shaft to stop the machine while a continuous sound is made in the mouth piece.

Mr. Edison says he will have no difficulty in making the machine bore a hole through a board; but we consider such an application of the machine of very little utility, as we are familiar with voices that can accomplish the feat without the mechanical appliance.

Le mégaphone. — D'après le *New-York Herald*, le professeur Edison vient de construire un nouvel appareil qui ne le cède en rien au téléphone, ni au microphone.

Cet appareil, qu'il désigne sous le nom de mégaphone, recueille à une grande distance les vibrations sonores les plus faibles et les renforce de manière à les rendre facilement perceptibles. Voici du reste un passage de l'article du *New-York Herald*, dont un des rédacteurs a assisté aux expériences décrites.

« Malgré la dépense d'intelligence que nécessitent les nombreuses merveilles en cours de construction dans son

laboratoire, le professeur continue chaque jour à perfectionner son mégaphone. Hier il le plaça devant son laboratoire, et donna les tubes de cautchouc à notre rédacteur pour qu'il pût constater lui-même l'étrange pouvoir de l'appareil.

Ensuite il s'éloigna à travers champs d'environ un mille (1,609 mètres), et se plaçant sur le sommet d'une colline il murmura : « Entendez-vous ceci ? » Les mots arrivèrent distinctement, quoiqu'une brise assez forte se fît sentir en ce moment. Lorsqu'il partit de ton ordinaire, les mots étaient entendus aussi distinctement que si la distance entre lui et son auditeur n'était été que d'un pied au lieu d'un mille.

July 7.8

as 16 to the inch, and the form of the thread should be square.

The shaft, A, is journaled in wooden standards, C, which are 1x1½ in. in transverse section. The distance from the base piece to the center of the shaft is 2½ inches. The base piece is 7x11½ inches face and 1 inch thick.

The standards may be screwed, or secured to the base by two common wood-screws, as shown. The clearance between the standards is twice the length of the cylinder, or 8 inches. A steel plate, a, is let to the bearing of the screw threads in the shaft, a, and is secured to the side of the standard, which is slightly beveled to conform to the pitch of the screw.

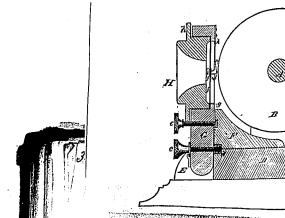


Fig. 2.

Under the cylinder and centrally between the standards a block, D, which is 3x3½ inches and 1 inch thick, is firmly secured to the base piece. The opposite edges of this block are covered by the cross pieces, E, and in the middle of the block a cap, F, is secured which is of the form shown in the engraving and 1 inch thick.

The screw, b, which are provided with lock nuts, b', pass through the front ends of the cross pieces, E, into metallic rings inserted in the edges of the diaphragm support, G, and form its pivots. This support is held in position by the screw, c, which passes through it and rests against a metallic button, which is inserted in the cap piece, F.

The diaphragm support, G, is 2½ inch thick and 3 inches

HOW TO BUILD A WORKING PHONOGRAPH.

WITH DRAWINGS MADE TO A SCALE OF HALF SIZE.

Now that Edison has invented the Phonograph, it is easy enough to make one, and every one wonders that it had not

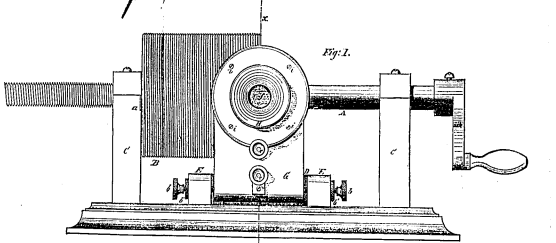

Fig. 1.

WORKING DRAWINGS FOR A PHONOGRAPH.—SCALE, HALF SIZE.

been done before. The Phonograph, truly wonderful as it is, is exceedingly simple and may be made at a slight expense.

The accompanying engravings represent two forms of a small phonograph which will work admirably, and do all that any of the large machines will do. In the illustrations, which are half size. Fig. 1 is a front elevation. Fig. 2 is a vertical section on line x x in Fig. 1. Fig. 3 is a plan view of a modified form of phonograph. Fig. 4 is a transverse section on line y y in Fig. 3. Fig. 5 is an end elevation, Fig. 6 a face view of the diaphragm, and Fig. 7 shows details of the screw cutting.

The shaft, A, is of iron, 1 and 2, 5/16 inch in diameter, 10½ inches long, and has on one end a 2 inch crank, and is threaded for five inches from the other end. The iron cylinder, B, which is 4 inches long and 4 inches in diameter, is bored axially, and secured to the shaft 3 inches from the threaded end, and has a screw cut upon it of the same pitch as that upon the shaft. The pitch of the thread should be 16 to the inch, and the form of the thread should be square.

The shaft, A, is journaled in wooden standards, C, which are 1x1½ in. in transverse section. The distance from the base piece to the center of the shaft is 2½ inches. The base piece is 7x11½ inches face and 1 inch thick.

The standards may be screwed, or secured to the base by two common wood-screws, as shown. The clearance between the standards is twice the length of the cylinder, or 8 inches. A steel plate, a, is let to the bearing of the screw threads in the shaft, a, and is secured to the side of the standard, which is slightly beveled to conform to the pitch of the screw.

Fig. 2.

Under the cylinder and centrally between the standards a block, D, which is 3x3½ inches and 1 inch thick, is firmly secured to the base piece. The opposite edges of this block are covered by the cross pieces, E, and in the middle of the block a cap, F, is secured which is of the form shown in the engraving and 1 inch thick.

The screw, b, which are provided with lock nuts, b', pass through the front ends of the cross pieces, E, into metallic rings inserted in the edges of the diaphragm support, G, and form its pivots. This support is held in position by the screw, c, which passes through it and rests against a metallic button, which is inserted in the cap piece, F.

The diaphragm support, G, is 2½ inch thick and 3 inches

Fig. 1.

WORKING DRAWINGS FOR A PHONOGRAPH.—SCALE, HALF SIZE.

wide, and is bored out to receive the diaphragm, f, and mouthpiece, H. The opening in the support, G, is of two diameters; the larger one, which receives the mouthpiece and diaphragm, is 2⅝ inches in diameter, and the smaller one nearly 2 inches, leaving a flange, g, which is 3-16 in. wide and ⅝ in. thick, and leaving 2 inches of the diaphragm exposed.

The mouthpiece, H, has an annular bearing surface which corresponds in width to the flange, g. The smaller part of the opening through the mouthpiece is 2½ in. in diameter.

The mouthpiece has a flange, h, for receiving screws, i, by which it is secured to the diaphragm support.

The diaphragm, f, is clamped between two rings of blotting paper, and is damped by two or three pieces, f', of elastic rubber placed between it and the inner surface of the mouthpiece, H.

A delicate wooden spring, k, having the head or mallet, e, is secured by screws to the diaphragm support, G, and the

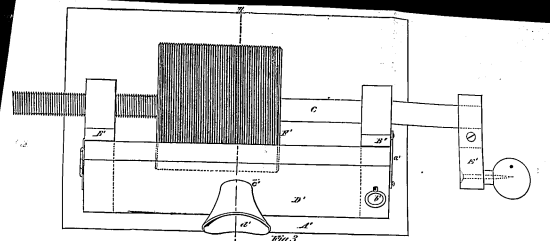

Fig. 3.

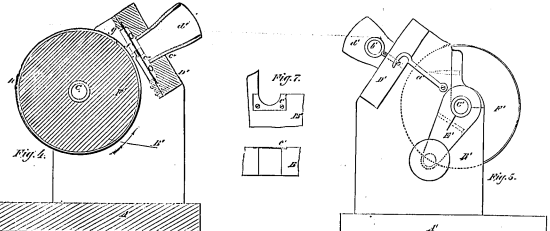

Fig. 4.

Fig. 7.

Fig. 5.

WORKING DRAWINGS FOR A PHONOGRAPH.—SCALE, HALF SIZE.

bevel, l, rests upon a thin piece, m, of elastic rubber, which is placed upon the center of the diaphragm.

The best material for the diaphragm is thin ferrotype plates, procurable at the photographer's. The head, l, is filed to a sensitive mouth, n, which projects about 1-16 in. and is quite sharp. The point, however, should be slightly round and shaped somewhat like the point of a leather awl, with the edge arranged parallel with the axis of the cylinder. The point of the point must be very slight indeed, and the mouth must always be kept in good condition. If the needle is too sharp it will cut and scrape the tinfoil. If too dull, the articulation will be muffled. The needle may at any time be sharpened by drawing it from the handle instrument by using a small abrasive slip. Before placing the tinfoil on the cylinder the needle must be adjusted by the

Fig. 6.

screws, k, so that it will strike exactly in the center of the space between the screw threads.

The tinfoil used with the instrument should be rather more than 2 inches square feet to the pound—and it should be cut into pieces 2 inches square.

The foil is mounted out on a glass plate and wrapped smoothly around the cylinder, and one end, after being greased or coated with a little shellac varnish, is lapped over the other end and the joint is carefully smoothed.

It is obvious that the cylinder, when tinfoiled, must be lapped depends upon the direction in which the cylinder is turned. While the cylinder may be turned either way, it is found preferable to turn it in a right-handed direction, and the foil accordingly should be lapped from right to left.

Having placed the tinfoil, the diaphragm is adjusted by means of the screws e e, so that the needle point will make a slight groove in the tinfoil, as the cylinder is turned. After this adjustment the screw e need never be changed.

Now, by speaking rather loudly in the mouthpiece, and at the same time turning the cylinder, the speech will be recorded upon the tinfoil. After loosening the screw c and the cylinder may be turned back to the point of starting. The needle may again be brought into contact with the foil by turning up the screw c, when, by turning the cylinder forward, the speech or other sounds will be reproduced.

It is found advantageous to speak to the instrument through a short tapering tube, the smaller end of which is ½ inch in diameter and the larger end 1¼ inch in diameter. The tube should be about 4 inches long.

When the instrument is made to speak a coiled paper resonator, 16 or 18 inches long and 3 or 4 inches diameter at the larger end and ½ in. diameter at the smaller end, should be inserted in the mouthpiece, as it greatly reinforces the sound.

Figs. 1 and 2, inclusive, represent a phonograph for which the standards may be purchased for $2.50. In this instrument the base piece is 7x11½ inches and 1 inch thick. The standards, B, are of the form shown in the engraving, and 1 inch thick. They support the shaft, C, which is 5/16 from the base, and cut all diagonally to receive the diaphragm support, D', which is hinged at one end and fastened by a hook, a', at the other end.

A screw eye, b', having its point filed off, is screwed through the free end of the diaphragm support and rests against the standard, B', and serves as an adjusting screw for regulating the needle. There is a ⅜ inch hole, c', exactly in the middle of the part, D', for securing the mouthpiece, d, and in the under side of the part, D', concentric with the hole, c', there is a shallow circular recess, e', which is 2 inches in diameter.

The shaft, C', is made of a piece of mandrel drawn brass tubing, 10½ inches long and ⅜ inch external diameter. It needs no turning, and it may be threaded by any steam or gas fitter. The length of the threaded portion should be the same as in the phonograph described above, but the lead may be somewhat coarser, say 14 or even 12 to the inch. The nut is made with a steel plate, e', screwed to the standard as in the other case.

The crank, F', is of wood, and is split from the shaft toward the handle and clamped tightly on the shaft by the screw shown in dotted lines.

The cylinder, B', of this machine is made of piece of pasteboard, and is turned off in the frames.

The method of making the cylinder is as follows: Drill two holes through the shaft at right angles to each other and insert two short pins, which will hold the cylinder in place after it is cut.

Strike two concentric circles on a piece of pasteboard, one 3½ inch and the other 4½ inches diameter. Put 7 inches of the smooth end of the shaft through the 3½ inch hole, and support the pasteboard in the middle of the shaft in vertical and at right angles to the pasteboard. Take a piece of sheet, smooth paper, 4 inches wide and 18 or 20 inches long, and form it into a cylinder 4½ inches diameter, and fasten the overlapping ends by means of pins or a string, and set it upon the 4½ inch circle on the pasteboard. Secure it in place with a little plaster of Paris.

Take a bucket viewed about 1 quart of water. Sprinkle into it 4 lbs. of very fine plaster of Paris, allow it to settle, pour off the surplus water, stir the latter quickly, but be careful that it does not become filled with air bubbles; pour the plaster into the paper cylinder, and allow it to set; when it becomes hard and before it dries, remove the paper mould, and place the shaft, C', in the bores in the standards and secure the box caps by a screw as shown in the end elevation (Fig. 5).

Fit a plug to the circumferences hole, c', and drive through it a turning chisel. Block up the free end of the part, D', and turn the shaft.

The cylinder revolves under the chisel, and is at the same time moved lengthwise by the screw. The machine is thus quickly converted into a lathe. By gradually lowering the chisel the cylinder is reduced to a uniform size both ways, and the cylinder will be reduced in diameter as much as may be necessary.

When it is 4⅛ inches in diameter, it is removed from the frames and dried in a warm (not hot) oven. When dry, and while it is warm, it is coated with paraffine, which is allowed to soak in.

When it becomes cool it is placed in the frame, and a V-shaped thread-cutting tool is substituted for the turning chisel, and the thread is cut in the surface of the cylinder by running the cylinder to revolve under the cutting tool as in the case of turning.

The thread-cutting tool must take very light chips, otherwise the cylinder will be rough.

The V-shaped grooves need not be deep, and the top of the thread should be wider than the groove. The diaphragm, f, is clamped between paper rings, over the recess, e', by means of a thin board, g, having a circular aperture which corresponds in diameter with the recess, e'.

The diaphragm is damped with short pieces of rubber tubing, and the needle is inserted in the same manner as in the machine shown in Figs. 1 and 2.

The mouthpiece is of porcelain, such as used for speaking tubes.

The tinfoil is wrapped around the cylinder and lapped as shown at A.

The arrow indicates the direction in which the cylinder must be turned.

A NEW ACOUSTICAL APPLIANCE.—The traffic over the elevated railway which disfigures New York is attended by great noise, which seriously interferes with business and comfort. A remedy for this is being sought, and the assistance of Mr. Edison, inventor of the phonograph and other electrical appliances, has been secured, and at present he is making investigation with a view of putting an end to the disturbance. He stated the other day that he had not yet found out all the sources of the noise produced by the trains, and until he had fully determined what the causes of the noise were, he could not act upon suggestions. He has, however, experiments, which would enable him to find out the noise, by which he can determine the character of the sound waves, and then get at the causes of the offensive roar. This instrument Mr. Edison described. It consists in part of a funnel to collect and condense the sound vibrations. At the small end of the funnel is a diaphragm which is made to vibrate by the sound. A cylinder similar to that used in the phonograph is placed near the diaphragm. About the cylinder is wrapped a piece of paper, which has been blackened by being held over the flame of burning charcoal. A straw is fastened to the funnel diaphragm in such a manner that the point falls on the blackened paper. As the cylinder is turned, the sound vibrations are traced by the straw on the paper in such a manner that they are plainly visible. The instrument is called the "phonautograph." By its use seconds of sound vibrations for any desired length of time can be easily made. These records, Mr. Edison believes, will enable him to determine the causes of the peculiar roar produced by the trains of the Metropolitan Road. He intends to use the phonautograph both in the cars and on the ground under the track. *N.Y. Sun 5/5/78*

THE PHONOGRAPH.—We hope to give an account of Messrs. Preece and Stroh's researches in vowel sounds in our next. *L.E. 7/5*

By V. DVORAK

[Translated from Annalen der Physik und Chemie, Band III., No. 3, Gustav Agren, November 18, 1877. With a note by Alfred M. Mayer.—*American Journal of Science and Arts.*]

(1.) *Acoustic repulsion of resonators which are open at one end only.*—In a previous article "On Acoustic Attraction and Repulsion," I have conclusively proved by theoretic considerations, as well as by experiments, that the average pressure at the node in a column of air vibrating in stationary waves cannot be equal to zero as long as the amplitude of vibration is not infinitely small.

In a resonator open at one end, as for example a cylinder, we find a node at the closed end. In the interior of the cylinder near the closed end there exists a greater pressure than on the outer surface of this end, which is touched by the outside air, as can be easily shown by means of a sensitive manometer.

To obtain resonance the opening of the cylinder is turned toward the source of the sound, and the cylinder is then repelled by the excess of pressure within. Resonators not having a cylindrical form, but open at one end, are also subject to such repulsion. In my previous communication I have indicated means for observing the acoustic repulsion of resonators. As the method described there is not very sensitive, I have replaced it by the following. The resonators here employed are usually made of India rubber, moreover well known glass and tops the shape of the cylinder with a little paper tube, *A A* as one end, Fig. 1, *a*. This little tube may also be omitted as in Fig. 1, *B*; in that case

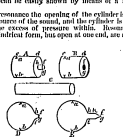

FIG. 1.

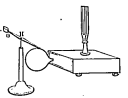

FIG. 2.

the resonator is tuned by increasing or diminishing the little opening, *f g*. Even a cylindrical tube open at one end, Fig. 2 *C*, may serve our purpose as a resonator. Spherical resonators of glass, Fig. 1, *D*, which a practical glass blower can make as light as paper resonators, are excellent. The note of the resonators is determined by gently blowing over the opening or by tapping.

The resonator is fastened with sealing wax to the end of a light wooden rod, the other extremity of which is provided with a counterpoise of lead, *G*, Fig. 2. The center of the rod has a glass cup, *H*, which rests on a needle point.

The best source of sound is a resonant box of a tuning fork, Fig. 2. The repulsion is so great that it is apparent even with an ordinary brass Helmholtz resonator, weighing, with the lead counterpoise, 142 grammes.* With every tuning fork we must first ascertain whether the air in the resonating box vibrates with sufficient energy, because this is not always the case even with accurately tuned forks. As the elasticity of the different boards which form the elastic system of the box is not equal, their vibrations may hinder the formation of the node at the bottom of the box; in this case the air on the bottom of the box will vibrate less than the air. We can easily ascertain this fact by successively applying the foot to the note of the fork and then observing whether the note is considerably weakened by partially covering the opening. If it is not, then the air in the box has but little vibration even if the base of the fork is powerful. I have, for example, two boxes with excellent tuning forks by König (of 256 vibrations per second), in which the air would in no way vibrate powerfully. The strength of the vibration of the air was considerably affected by the degree of tightness with which the fork was screwed to the top of the box. The air is always vibrated powerfully with a bow, and two bits of rubber tubing must lie on the bottom of the box. I generally use the fork A, of 435 vibrations per second, by König. Repulsion is then plainly visible with glass resonator at a distance of ten centimeters from the opening of the box. With a large C fork of König (of 128 vibrations), which sounds for more than ten minutes, it was apparent at a distance of twenty centimeters.

The resonators may be tested either by the re-enforcement of the sound produced with a tuning fork, or by the weakening of the sound on approaching them to the opening of the box.† It is not possible to obtain the repulsion of resonators from the prongs of a tuning fork alone, as their aerial oscillations are too weak. (Compare Dvorˇ, *ebdb*., p. 42.) I formerly tried in vain to obtain acoustic repulsion from vibrating bodies without the aid of resonance. I suspended small resonators, like that of a glass tube vibrating longitudinally and open at both ends, to a rock to increase the vibrating surface. The open end of the resonator was probably too near the end of the fork, and thus prevented a lowering of the tone and acoustic attraction instead of repulsion. Attraction is probably present in all cases and can manifest itself only when not counteracted by greater repulsion.‡ Later I obtained repulsion very easily in a longitudinally vibrating glass tube 127 centimeters long and 27 millimeters in diameter, on the end of which was a cork 46 millimeters in diameter. One of the resonators used was spherical, Fig. 1, B, and another cylindrical, C.

I also obtained powerful repulsion with a circular disk 21 centimeters in diameter and two millimeters thick, made by König. The plate was fastened in the center in a vertical position and made to vibrate in six segments, producing a tone of 208 vibrations. The resonator was made of stiff paper of the form of B, Fig. 1; *a* equal 80 millimeters, *c d* 140 millimeters, *f g* equal 17 millimeters, and its opening was placed in front of the center of a vibrating segment, or ventre.

(2.) *The Acoustic Mill.*—A continuous rotation is easily obtained on the principles of the acoustic repulsion of resonators by fastening four very light paper or glass resonators upon two wooden rods, *n, n', o, o'*, Fig. 3, crossing at right angles, and balanced on a glass cup; all the openings of the resonators

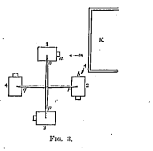

FIG. 3.

turn fronting one side in the direction of tangents. The whole apparatus is placed before the opening, *K*, of the resonating box and fork, in the manner indicated in Fig. 3. The open end, *a*, of resonator 1 is repelled from *K*; the closed end, *B*, of resonator 2 is attracted, but in general this attraction does not increase the rapidity of rotation, because it counteracts rotation the moment the resonator 2 has changed its position about 45°. It is therefore not possible to obtain continuous rotation by means of acoustic attraction, as I have shown by numerous experiments.‡ The resonance 1 continues to move by reason of its inertia and resonator 2 takes its place, being in turn repelled, and so on.

A very rapid rotation is obtained by using a large Kundt's tube and placing a small acoustic mill before its open end.

The glass tube (Kundt's), which vibrates longitudinally and produces the tone, is fastened in a heavy table, and protrudes only a short distance through the cork into the glass tube, placed upon a separate table so that its open end projects somewhat beyond the edge of the latter. The length of the rod was 127 centimeters, the diameter twenty-seven milli-

meters; the half wave length of its note, $\frac{2}{4}$, equals ten and

one-half centimeters. The length of the tube was 45 centimeters; the length of the vibrating column of air, corrected

for the open end, was $3\frac{2}{4} + \frac{1}{4}$, the inner diameter was five centimeters.

(4.) *The Acoustic Torsion Balance.*—If we hang by a silken thread, not provided with a resonator, like the beam of a Coulomb's torsion-balance, in a case having an opening in the side turned toward the resonator, we can demonstrate the intensity of notes having an equal number of vibrations by means of the repulsion of the resonating jar. For further experiments are necessary to test the practicability of this method.

The sound proceeded from an open pipe, having the note A (of 435 vibrations). To prevent the retreat of air which passed through the pipe into the resonating the resonator attached to the balance, we insert not the pipe exactly in the middle of its ends, and bind a thick membrane soaked with glycerine. To prevent the air, issuing from the mouth of the pipe, from impinging on the resonator, a board box is used, which surrounds the mouth of the pipe on all sides. This box is open on the side opposite the resonator so as not to impair the tone. The pipe is sounded by means of a Kinkle's acoustic bellows with a uniform blast of air. The distance

* This is perhaps connected with a connection of the aerial vibrations with the electric current. The ebb tide of the sound vibrations disappears in support to work.

† These experiments were also described in a previous communication, in the apparatus represented, Fig. 3, repulsion is easily over-rated into attraction by disturbing the opening of the resonator with wax, and so throwing it out of tune.

‡ Instead of resonator, No. 3, I used vertical pasteboard tubes, varying in length and inclination, allowing any position, notwithstanding the fact that there was a pasty string acoustic attraction for each separate

of the resonator from the mouth of the pipe must be at least two or three centimeters, to avoid a change of pitch.

(5.) *Production of Currents by Sound.*—It may easily be proved by simple theoretic considerations that the mean pressure on the walls of a column of air is greater than at its center, and that it steadily diminishes in passing from the node to the center, provided that the amplitude of vibration is not infinitely small.

It would seem that this difference of pressure would be neutralized by the passage of the air from the node to the center. There would then be produced a mean pressure in the whole column, which would be greater, however, than that of air at rest. Consequently air would issue from the opening of the vessel in which it forms stationary waves. I have not succeeded so far in making the whole process clear, or in realizing the perfect balance of pressure-laws place. The manometer gives evidence of a slight excess of pressure even at the center, but this excess increases as we pass to the node. All my previous experiments show a continuous current of air from the node to the center, and in a direction contrary to that of the principal current, so that the whole air is in the tube in circulation. The cross-section of the tube of equal current is nearly as great as that of the tube, while that of the secondary current is a very narrow ring.

The excess of pressure as shown by a manometer at the node is always less than the theoretical pressure, because in the latter the air is not supposed to issue from the node and to equalize the pressure. Of course the excess of pressure at the center is not equal to zero, as theory requires. Probably the friction of the walls has much to do with these phenomena. It may be expected from what has been said that the air will issue from the vessel in which it vibrates in standing waves. The manometer shows in the first place that the excess of pressure is not equal to zero in the place of the standing wave, and further because a portion of the air immediately in front of the sounding particles of this stationary wave rushes, and because there is always a small excess of pressure even in the vessel in ordinary waves. There is no doubt that a partial equalization of pressure takes place at the opening; experiments show, furthermore, that there is a continuous exit of air which, as in Kundt's tube, is probably neutralized by a secondary and contrary current.

The air-current can easily be proved, as follows: A sphaerulating flask, the resonator is placed before the resonant face of a vibrations are given to the fork, when the smoke will be seen to rush from the resonator.

The current of air proceeding from a resonator is well shown by means of a Chladni plate, by means of hydrogen, which accumulates upon the vortex in little heaps when a plate is sounded. If now we place the opening of a bottle, or bottles of 4 resonator, B, over such a heap, the hydrogen will be immediately blown about in a circle and may be scattered in any direction by giving suitable inclination in the resonator. A glass plate held over a heap of lycopodium produces the opposite effect by causing it to coagulate.

I have succeeded in producing comparatively strong currents of air in still another manner, but I have not yet found an explanation of these complicated phenomena.

A cone made of stiff paper was held with its large end opposite the opening of a large Kundt's tube. The size of this cone may vary, but itseffect is greatest when it vibrates to the same note as the Kundt's tube, and when a resonator is at both ends; the diameters of its open ends are thirty-seven and seven millimeters, and its length ninety millimeters.

When the Kundt's tube begins to sound lustily a current of air issues from the narrow end of the cone with such violence that it easily blows out the flame of a candle at a

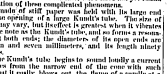

FIG. 4.

distance of twenty centimeters. This current reduces through the cone with a peculiar noise and is easily felt with the finger.

The cone may be replaced by a cylinder having the width of the Kundt's tube, open at the end turned toward the latter, and closed all but a small hole at the end, but the current issues less briskly; nevertheless it will move a small wheel with vertical paper vanes, Fig. 4.

In the experiments with the tuning forks, it is essential that the cone should vibrate to the same note as the fork, otherwise the current is too weak. For the fork A (of 435 vibrations), the openings of the cone have diameters of 82 and 7 millimeters, and the length 373 millimeters. The opening at the apex of the cone must be very small to obtain an appreciable current.

On conclusion of this investigation, Dr. R. Klinkg kindly communicated to me that Mr. Alfred Mayer in New York [Hoboken] had previously succeeded in producing continuous rotation by means of sound. The communication was as follows: "Professor A. M. Mayer showed me a very similar experiment last summer (1870). He suspended by a thread two large well-tuned flasks attached to a rod, and caused the whole apparatus to revolve by means of a tuning fork. I informed him in consequence that you had previously demonstrated the phenomena of repulsion in resonators, for he was not acquainted with your paper* on acoustic attraction and repulsion."

NOTE BY PROFESSOR ALFRED M. MAYER.

My connection with the discovery of the Sound-Mill is as follows:

In January, 1870, I made the discovery—first one not to a theoretic deductions—that there was more pressure on the inner surface of the bottom of a resounding cavity than on the outer surface of the bottom which touches the air. This I subsequently proved the truth of this conclusion by experiments on suspended resonators, and by observations on the motions of precipitated silica powder and films of soap-bubbles placed at various points in resonators of different

* Read before the R. Acad. Sci., Vienna, in 1873.

forms. My first publication of these results was on May 23d, 1870, on which day I read a paper on this discovery before the New York Academy of Sciences, and exhibited before the members an apparatus formed of a tuning-fork, a box of wood, with a resonator attached to sounding an organ-pipe, of Professor Dvorik's paper. In tune with these resonators, or a fork on its resonant box, in tune with these resonators, or a fork on its resonant box, in tune with these resonators, and they were successively repelled. At the same meeting a continuous rotation was exhibited. At the same meeting this experiment was preceded by those in the Scientific American, etc., in connection.

On the 8th of July, 1870, there appeared in the Scientific American a report of this meeting of the Academy, in which my experiments in Acoustic Repulsion are thus referred to:

"In the next place, Professor Mayer exhibited an apparatus constructed by him to produce motion by means of sound pulses. Four glass resonators on cross-arms were suspended by means of a string. On sounding an organ-pipe, in tune with the resonators, and bringing it oppositethe mouth of one of them, the resonator was repelled and the apparatus commenced to rotate. This experiment was the more striking, from the fact that, as far from any current of air proceeding out of the mouth of the organ-pipe, the air is actually sucked in, as may be rendered visible by means of smoke from a cigar. The smoke is carried up the pipe even when the latter is closed at the top with cotton wool so as to smother it of sound. On substituting flasks of cardboard for the resonator, they were thrown up to the mouth of the organ-pipe with considerable force. When two miles powder was placed in the resonators, it was thrown into violent motion on sounding the pipe."

In the same month, July, 1870, Dr. Rudolph Konig visited me, and I exhibited the same experiments before him.

The discovery of the acoustic repulsion of resonators and the invention of the sound-mill were made entirely naturally by Professor Dvorik and myself. It is another instance of mind—even so far distant as Agram and Hoboken—acting in the same path of research by the natural growth of science.

Dimensions of the resonators and reaction wheels used in millimeters: (1.) Fork C, of 128 vibrations. Glass resonator of form E, Fig. 1, a. 6, equals 90; b, f, 25; b, k, 20; k, f, 30; f, g. 8. Its weight, together with its leaded counterpoise, was 72 grammes.

(2.) Fork A, 435 (vibrations per second). (a.) The glass resonator used in the experiments represented in Fig. 2, and to show the currents of air by means of smoke, was of the form D, Fig. 1. a. d equals 58; b, f, 22; f, g. 10. (b.) The glass resonators of the acoustic mill were of the form D, a d equals 31; b, f, 12; f, g. 5. The length of the arms from the middle of the glass cups to the middles of the resonator was 52 millimeters. The weight of whole wheel was 23 grammes. (c.) Paper resonators of the acoustic mill, Fig. 3, were of the form A, E, a. d; a. e; d. m; d. y; e. n; y. z; 8 millimeters. The length of the arms was 65; the weight of the wheel 9 grammes.

(3.) Kundt's tube, $\frac{2}{4}$ equals 105 millimeters. The glass resonators of the acoustic mill were of the form D, Fig. 1, a d equals 51; b, f, 21; f, g. 7; length of the arms, 30 millimeters.

It is a striking fact that very small resonators may give very deep notes; with fork C a wooden glass resonator of the form H, Fig. 1, in which a. b equals 21; b, f, 11; and f, g. 4 millimeters. The volume was about 1/1000 of that of the resonator box of the fork, to which the resonator was tuned. Notwithstanding its smallness it showed acoustic repulsion.

[1871.]—Phonograph.—After the number of failures that have been recorded it is quite refreshing to hear of your success. Adjustment of the points, without looking at them, is simply a matter of practice. My method is to screw up the nut slowly until one hand, while with the other I turn the cylinder, I can hear the point just touch the groove of a turn; I can tell by the sound of the scratch when the adjustment is right. Of course it is easy to add regulating stops, but they will be found to require frequent alteration, as the instrument is very sensitive to change of temperature and moisture.—Sheldon Bidwell.
Ph. vol. —, page —, calc.

The Phenograph.—In his study of the phonograph record, Mr. Edison finds that he can recognize certain known sounds from their indentations when there sounds are made by the same kind of voice. In spite of the irregularity existing in the points of the same sounds uttered by different persons, or by the same person under different conditions, he claims that the record of any one sound can be distinguished from any other sound. Between the records of vowel sounds very little difference could be detected. For some vowels the indentations were deeper at one end than at the other; giving to the characters the shape of eggs, pears, and Indian clubs. This is usually the case with the vowel E. The deepest indentations are made by consonant sounds—on account of the explosive force with which they are uttered; P, especially being distinguished by the pit which begins the imprint.

New Phonographic Experiments.

Our [illegible] observations on the waveforms of articulate sounds may be made by Edison's phonograph. We have submitted the indentations of the [illegible], which had received the impressions of different sounds, to microscopic examinations, but the insignificance produced in them are on such a very minute scale, that even the microscope does not plainly reveal the differences, without peculiar preparation.

Prof. Fleeming Jenkin, assisted by Mr. J. A. Ewing, has obtained a large series of necklaces upon lamp-black paper, by which the waveforms of different sounds have been shown. Some of these results Prof. Jenkin has laid before the Royal Society of Edinburgh, Scotland. The vowel sounds in the phonograph are found not to depend on the speed with which the cylinder of the phonograph is turned, the distinct vowel being heard however much the pitch of the note may be altered by more rapid or slower turning of the instrument. He found that the phonograph would be produced to produce the French a, always converting it into the sound of oe. On the black-board Prof. Jenkin has exerted some of the commonest forms assumed by the sound-waves, one of the most interesting being that of the letter r. In the case of the broad sound of a, it was shown that while with most ordinary voices the wave took the form which might be described as having two humps, a rich bass voice had been found to give a wave-form much more intricate, showing four distinct humps in each re-current period of vibration. It was found that the phonograph gave vowel sounds as well when the cylinder was turned backward reversed; and, encouraged by this, the consonants were experimented upon, giving the same result. Even with a consonant at the beginning and end of a syllable, as, for instance, *bed*, it was rather unexpectedly found that the word would be correctly repeated either way, showing the identity of the sound.

Prof. Jenkin gave some amusement by describing the effect of reading words backward, stating that with careful observation every sound could be detected, for example, "association," which, when the cylinder was reversed, could be distinctly heard as "noos-hel-ass-see." Mr. Ewing—which he said Mr. Ewing could in "Edinburgh"—which he said Mr. Ewing could pronounce backwards, though he could not—the different sounds could also be distinguished. Words and sentences which, when pronounced backward or forward sound the same, were tried. Thus was tried the well-known sentence, "Madam, I'm Adam," with which Adam is traditionally alleged to have saluted Eve; and "Madam, I'm Adam," although spelled the same both ways, did not sound the same in the phonograph, the diphthongal sound of the "I'm" giving a sound like "aym."

It is obvious from Prof. Jenkin's experiments that some interesting points in acoustics may yet be settled by means of this extraordinary instrument.

[31116]—Phonograph.—I grind my points on an oil-stone to an angle of 45° or 60°, and then polish by rubbing with a bloodstone. I have even a phonograph with a ruby or sapphire point; I forget which. The ruby is the best, as it is harder than the other materials, and so polishes more easily and quickly. Indiarubber tissue under the tinfoil reduces the scraping sound, but it also diminishes the power of the instrument very considerably. On the whole it is best to use the tinfoil without backing. The highly polished points and smooth tinfoil respond lightly upon the cylinder with a practically scraping sound—a very subtle, and does not interfere at all with the performance of the instrument. With a single diaphragm and in the manner described, for me a few weeks was the acting circuit to find where, on the tinfoil, I could get the loudest sound. Speaking is the best; I still prefer two diaphragms for general use. Try steeper tinfoil. See that the point on it at spring turns slightly forwards, and do not make it or furrows too deep.—SHELFORD BIDWELL.

THE PHONOGRAPH AND VOWEL SOUNDS.

III.

WE now pass to the general conclusions which may be drawn from our experiments. In the first place it seems clear that vowels do not depend on pitch alone or on the simple grouping of partial tones independently of absolute pitch. Before the constituents of a vowel can be assigned, the pitch of the prime must be named. But on the other hand the pitch of the most prominent partial of the group is not alone sufficient to allow us to name the vowel in which it appears: to do this we also require to be told the relation of the constituent partials to one another.

The sound *ā* consists mainly of one tone generally lying in the region above *c*.

The sound *ā* requires at least two partials; when there are only two important ones these lie in the region between *g* and *f'*; a region covering nearly two octaves. Indeed the upper limit may extend above *f'* with a tenor or woman's voice. Other partials than the prime are reinforced by the mouth-cavity over all this region. This great range is obviously a distinguishing mark of *ā* as compared with *ō*, perhaps *the* distinguishing mark; for when *ō* and *ū* are sung at various pitches, the most prominent partial, first of one letter and then of the other, is highest, and the most prominent partial of both sounds may be on *f*5, the characteristic tone of *ā*. An *ō* sung on *f*5 may even have the true *f*5 more strongly present in it than an *ō* of the same pitch. When *ō* was sung by voice 1 on *f*5 the prominent partial was the second, when *ō* was sung at the same pitch by the same voice the second partial was still the most prominent. Thus for voice 1 the distinction between *ā* and *ō* rests on the fact that in the pitch of strongest reinforcement, that is the fact that the prime was larger for *ō* than for *ā*. When *ō* was sung at *f*5 the prominent partial was the prime; when it sang *ā* the prominent partial was the second, the prime being also strong. Thus, for voice 1, the distinction lay in the fact that the prime was much smaller for *ā* than for *ō*. It is obvious here that the ear cannot have been guided by the absolute pitch of the reinforcement to the distinction between *ā* and *ō*. At this pitch the distinction lies in the fact that *ā* contains two strong partials (the prime and second), whereas *ō* contains only one (the prime or the second). The argument is not weakened by saying that the *ā* of one voice was not the same as the *ā* of the other. Identically the same it cannot have been; nevertheless, on higher or lower notes the two voices agreed as to the composition of *ō*, and generically the vowels were certainly the

[Continued from p. 397.

same. There remains the fact that speakers and hearers were unconscious of any general change in the vowel *ā* when the pitch of the strongly-reinforced partial changed by a whole octave.

On the other hand, it is equally clear the voice, in singing a given vowel at various pitches, does not simply produce a certain constant group of relative partial tones. Possibly, indeed, the ear might recognise a single tone, especially if very feebly sec supported by higher harmonics, as a kind of *ā* out side the region within which the human voice forms *ā* in that way. Thus Helmholtz, in his *Tonempfindungen*, says that the single tone 6*c*, when sounded alone, gave a very dull *ō*, much duller than could be produced by the voice. It would be rash to assert before the prime where voice 1 proved to make *ō* by reinforcing the octave. Quite similarly it is easy to see that the group consisting of a prime and its octave might be recognised as *ō* even when produced below the limits within which the human voice does produce this simple form up in singing *ō*. Our own impression as to the re-ult of running the phonograph down is to speaking them when it is spoken to, supports this view, but we do not desire to lose any inference on that. Certainly *ō* and *ū* are sounded in this manner in not the human *ō*.

Moreover, we find a very decided re-semblance in the relative constitution of *ō* at a low pitch and *o*' or *ū* at higher pitches, *ō* in the neighbourhood of *f*5, and *ū* in the neighbourhood of *f*, and *ō*, *ū* are practically similarly constituted. Our experiments on *o*' and *ū* are not sufficiently extended to allow any very general conclusions to be drawn, but they are sufficient to show that between certain vowels the main distinction must lie in the absolute pitch of the reinforced group of partial tones.

We may thus bring back to our original statement that in distinguishing vowels the ear is aided by two factors, one depending on the harmony or group of partials, and the other on the absolute pitch of the constituents. It seems not a little dissimilar in their relative and absolute composition as those represented by the curves of Fig. 1.

We are forced to the conclusion already adopted by Helmholtz and Donders that the ear recognises the kind of cavity by which the reinforcement is produced; that although the sounds which I call *ā* and *ō* are both vowels, and are both recognised as generically represented by the curves of Fig. 1.

We are forced to the conclusion already adopted by Helmholtz and Donders that the ear recognises the kind of cavity by which the reinforcement is produced; that although the sounds which I call a practically vowel. But we have to consider what light the experiments throw on the kinds of cavity that are required for certain vowels. The cavities are clearly distinguished in virtue of two distinct properties: first, the pitch of their maximum reinforcement which they are capable of producing. This latter property has, we believe, been hitherto much neglected.

Prof. Cleve Brown's experiments prove that a *constant* cavity is capable of producing the constant vowel *ā* over a large range of voices singing *ā* appear to exhibit differences with various human which new partials are sometimes introduced somewhat abruptly; tend for the sound *ā* it seems certain that the cavity is tuned, that is to say, that the pitch of its proper tone is nearly the same when the vowel is sung on different pitches. The remarkably strong *fourth* partial in all the duplex *ā*'s of Table VI. may be noticed as favouring the view that in each of these examples the end cavity had been adjusted so as to be in unison with the second partial. We may describe the *ā* cavity as an adjustable cavity with a very limited range of resonance, whose effect is to reinforce strongly only one partial lying above *a*. It is possible that this cavity may keep itself constant throughout the very limited range of pitch employed in ordinary speech, but when that range is increased as in singing, a certain tuning seems indispensable.

If we assume that the *ō* cavity is absolutely constant, we must describe it as a cavity capable of reinforcing more or less strongly tones lying anywhere between *g* and *f*'. This cavity

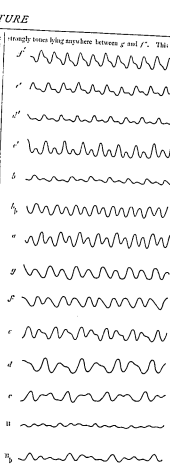

FIG. 1.—*Wave-forms of ō Sung by the same Voice at Various Pitches.*

[1] We reproduce this week the figure which accompanied Prof. Jenkin and Ewing's first paper, on "The Wave-Form of *Ō*," p. 310. It shows the delicate forms of the curves with greater exactness, and will enable the reader to understand more clearly the value of the conclusions come to by the authors.—ED.

LE MÉGAPHONE

Nous avons reçu de New-York le dessin du *Mégaphone*[1] pris sur l'instrument établi par le professeur Edison, à Menlo-Park. L'appareil possède, paraît-on, une puissance vraiment admirable. On est parvenu à converser à une distance de 1 à 2 milles, en causant dans le porte-voix, sur un ton ordinaire. La construction du mégaphone est aussi simple que ses effets sont merveilleux. Il est formé de deux simples entonnoirs de carton — ceux d'Edison ont 2 mètres de long et 1 m. de diamètre à leur plus large extrémité — terminés chacun par un tube de caoutchouc dont le bout se met dans l'oreille. Entre ces deux entonnoirs se trouve un porte-voix de construction semblable aux porte-voix ordinaires, si ce n'est le pavillon qui est beaucoup plus ouvert. Le plus petit

Bibliothèque Nationale de France

chuchotement est entendu au moyen de l'appareil à quatre cents mètres de distance.

Malheureusement, cet instrument ne sera d'aucune utilité pour les personnes affligées de surdité; ses dimensions l'empêchant assurément de devenir jamais un « instrument très-portatif et susceptible d'être placé sur les grands ou dans la poche. »

[1] V. *Monde de la Science et de l'Industrie*, page 103.

LE MÉGAPHONE

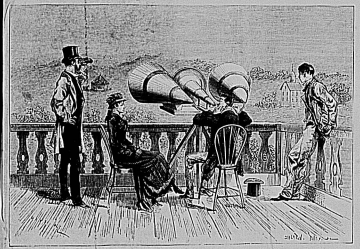
THE PHONOGRAPH.—The Abbé Cerbenal, of the Belsunce School, Marseilles, has been experimenting with the phonograph, and concludes that the recording and reproducing diaphragms should be distinct, the stiff, hard foil, the latter a delicate membrane like that of the ear. The foil could be made from a copper and corroded afterwards by acid so as to obtain a hard metal cast; but this is necessarily a defective process. The Abbé therefore employs albumen spread upon paper or other base, instead of the wax applied to the hardened. The soft albumen record is afterwards whose dims vary in depth with the intensity of the sounds he suggests the use of Bavaria wheat instead of a vibrating plate.

LE MÉGAPHONE DE M. EDISON

Le porte-voix qui, pendant deux siècles au moins, a été usité pour transmettre des sons à une grande distance, est très-employé sur mer; il est aussi sur terre pour faire entendre des sons destinés à dominer tout autre bruit. Il est à peu près certain que le porte-voix est d'origine nautique et qu'on en doit l'invention à Samuel Marland en l'année 1670.

Kircher, dans son *Ars magnæ et umbræ* et dans *Phonurgia*, mentionne une espèce de porte-voix, construit dans des dimensions gigantesques et désigné sous le nom de cor ou cerne d'Alexandre. D'après Kircher, cet instrument permettait à Alexandre le Grand d'appeler ses soldats à la distance de dix milles. Le diamètre du cercle devait être de 8 pieds et Kircher conjecture que l'instrument était monté sur trois solives.

Au siècle dernier, un professeur allemand, nommé Huth, fit un modèle de cor et trouva qu'il remplissait l'office d'un puissant porte-voix; mais nous doutons fort que les sons, passant par cet instrument, aient pu être portés à des distances réellement considérables.



Le Mégaphone de M. Edison.

Le cornet acoustique qui est la contre-partie du porte-voix, a été fabriqué dans différentes formes durant les deux derniers siècles; mais aucune des formes aujourd'hui existantes ne l'emporte sur un tube simplement conique évasé et ayant un orifice pareil à celui d'une cloche.

Le professeur Edison, dans ses recherches sur le son, a fait des expériences nombreuses et intéressantes; l'une des plus curieuses consiste dans le fait d'une conversation soutenue à 1 mille et demi ou 2 milles (2 ou 3 kilomètres) de distance sans autre appareil qu'un petit nombre de cornets en carton. Ces cornets constituent le *mégaphone*, instrument merveilleux tout à la fois par sa simplicité et par les effets qu'il produit.

Notre gravure représente l'instrument tel qu'il est installé sur le balcon du laboratoire du professeur Edison, à 1 mille et demi (plus de 2400 mètres) de distance; à l'endroit indiqué par les deux cavaliers sur notre dessin, se trouve un instrument tout à fait semblable à celui qui est représenté au premier plan.

Les deux plus grands cornets ont 6 pieds 8 pouces de long et 27 pouces 1/2 de diamètre à leur extrémité la plus large. Chacun de ces entonnoirs est muni d'un tube acoustique flexible, dont l'extrémité aboutit à l'oreille. Au milieu, le porte-voix ne diffère pas essentiellement du type ordinaire des instruments de ce genre. Il est un peu plus long et son orifice en forme de cloche est plus évasé. Avec cet instrument, on peut aisément converser à la distance de 1 mille 1/2 à 2 milles (de 2400 à 3200

THE PHONOGRAPH AND THE TELEPHONE.—In a communication to the *Comptes Rendus* M. Bouillaud discusses the question whether the phonograph repeats words on a principle similar to that on which differ notably from those which have been uttered, which is not the case with words repeated by an echo. Touching on the telephone, he expresses doubts as to the part played by the electro-magnetic machine.

M. Bouillaud, the eminent French savant who lately pronounced the phonograph a ventriloquial fraud and had his doubts set at rest for at the séance of October 7th, Count du Moncel again exhibited the "singing condenser" and the phonograph before the entire Academy, bearing it in the members to make the experiments themselves.

THE PHONOGRAPH will henceforth be sold in America to all purchasers, without any royalty to the Phonograph Company, for 100 dols. (£20 or 500 dols. (£16), according to the finish of the instrument.

1878.] THE LOGOGRAPH. 65

experiment might be tried of an analogous kind, by moving the hydrogen with a brush, or other mechanical means, to see if it has the same effect as the gases. I am sure you will all agree that we should return our thanks to Mr. Edmunds for his kindness in showing us this battery.

A vote of thanks was unanimously accorded to Mr. Edmunds.

Mr. W. H. Barlow, F.R.S., V.P. Inst. C.E., then gave a description of the Logograph. He said—The small instrument I have to show you is not altogether a new one. It is scientifically getting rather aged—about four years old. This instrument, I may confess at once, owes its origin to an attempt to make something which would do short handwriting instead of employing the services of the gentleman who sits there. We have failed in doing that, but it has certainly served some purpose. It has served the purpose of illustrating certain features connected with the articulations of the human voice. Everybody knows that, in speaking, the air contained in the lungs is sent forth from the mouth in spurts of different magnitude and with different degrees of velocity and intensity. I may say that forty years ago I first thought of this when I saw an old Turk smoking his pipe. The Turks, as you know, inhale the smoke into the lungs, and, as they speak, you can see all the action of the air coming from the mouth. I was also informed of the extraordinary sensitiveness of some of the instruments used for registering indicator diagrams of the steam engine at very high velocities, and it occurred to me to put these two things together and form a delicate apparatus, and so obtain indicator diagrams showing the relative powers of the different *syllables* uttered by the human voice.

The instrument I formed was that now before you. It consists of a small speaking tube, the end of which is enlarged to a disc of about 2½ inches diameter. That end is covered with a piece of thin india-rubber, taken from a toy balloon. That membrane being stretched with a certain degree of tension, a light aluminium arm is made to press against it, the end of the aluminium arm holding a small sable brush containing colour; the speaking part of the instrument is, to a certain extent, similar to the telephone; the

THE PHONOGRAPH AND THE TELEPHONE.—In a communication to the *Comptes Rendus* M. Bouillaud discusses the question whether the phonograph repeats words on a principle similar to that of the echo. He asserts that, as regards force, tone, speed and quality, the words of phonographic origin differ notably from those which have been uttered, which is not the case with words repeated by an echo. Touching on the telephone, he expresses doubts as to the part played in the electro-magnetic machine.

M. BOUILLAUD, the eminent French [illegible] pronounced the phonograph a remarkable [illegible] the microphone an accepted humbug [illegible] had his doubts set at rest, for at the soirée of the 7th, Count du Moncel again exhibited his [illegible] condenser" and the phonograph before the Academy, leaving it to the members to make experiments themselves. *Engineering*, 7 Feb.

THE PHONOGRAPH will henceforth be sold to all purchasers, without any royalty to the Company, for 100 dollars (£25) or 200 dols. (£50) according to the finish of the instrument. *Nature*

other part of the instrument causes a ribbon of paper to pass under that brush, and then speaking into the instrument you get a diagram of the utterances that are made.

[Mr. Barlow illustrated this—the mechanical action of the instrument being similar to that of the tape-printing telegraph—and passed the ribbon on for the inspection of the meeting.]

You see there (Mr. Barlow continued) the action produced by the sounds I have just given. I may mention some facts that I have obtained as to the absolute quantity of air consumed by this process. The horizontal movement is about half an inch for some of the letters, and the whole diagram is a very large and conspicuous one. I found on an average of experiments the quantity of air consumed for each syllable, or rather the average quantity of air for each syllable, is 1¼ cubic inch. It varies very much in different syllables. The quantity of air consumed was ascertained by taking a balloon of the cubical area of 513 cubic inches, and I found it took an average of 359 syllables to fill it. That brings it to an average of 1¼ cubic inch for each syllable. I also found the capacity of the ordinary breath is about 40 cubic inches, and that by taking an extreme breath you may bring up the quantity to 80 or 90 inches. I also found that you can speak against a pressure equal to that of two inches of water, but against a pressure of four inches it seems impossible to speak at all.

Having made these experiments, which resulted in showing the peculiarities of articulation, and how the different letters were formed, and what happened to them, it occurred that the marker I was using became fixed to the disc. That arose from having used goldbeaters' skin, which caused the attachment of one to the other. I found the consequence was to produce a vibration from the vowel sounds. [Mr. Barlow directed attention to a diagram on the wall illustrating

the vibratory action of vowel sounds as distinguished from the pneumatic action of consonants, and went on to remark.] These larger lines represent the consonant actions. You observe that following them is a fine vibration, and that vibration is the vowel sound, or rather I believe there is a certain organ which vibrates whenever the vowel sound is uttered. I think it is a kind of drone which is present whenever the vowel sound is uttered. A whisper is sufficient to make known the vowel sound intended, whereas whispering will make no vibrating action. The form of the diagrams produced leads to a good many curious questions, as to the action of vowels and consonants and compound letters, things which will combine and those which will not, and I have no doubt those who know something about the anatomy of the throat and the laws of sound will be able to get more out of this instrument than I have succeeded in getting.

The CHAIRMAN asked whether, in repeating the same words over and over again, the signs recorded are constant.

Mr. BARLOW: They are constant, subject to very minute variations that arise in this kind of thing. It is almost impossible to speak the same words exactly in the same manner each time. This instrument is purely phonetic, and however minutely your articulation differs at one time from another that difference is registered.

Illustrations were given of the diagram produced by the trilling the letter "r," also by repeating the same words two or three times.

The CHAIRMAN said he was struck with the great extent of the movement of this instrument. The movement was quite half an inch in some of the longer terms. It seemed to be necessary to place the mouth close to the tube.

Mr. BARLOW explained that it was necessary to do so in order that the full effect of the air might be brought into operation.

The CHAIRMAN: In other kinds of instruments of this description you do not place your mouth so close to the tube, but depend more upon the vibratory action of the air.

The thanks of the meeting were then unanimously accorded to

THE PHONOGRAPH AND THE TELEPHONE.—In a communication to the *Comptes Rendus* M. Bouilland discusses the question whether the phonograph repeats words on a principle similar to that of the echo. Mr. Barlow for his kindness in exhibiting his most interesting invention.

The CHAIRMAN then called upon Mr. W. H. Preece to give his promised description of

"THE PHONOGRAPH."

Mr. PREECE said: The instrument which has just been described to you by Mr. Barlow is a very fitting prelude to this wonderful instrument that has just come to us from across the Atlantic. The phonograph of Mr. Edison is an instrument which is constructed for the production or rather reproduction of sound by mechanical means. It differs from the telephone in this—that the telephone is an instrument that produces sounds at distant places by the aid of electricity; but in the first principles of the two instruments we have the same identical object, viz.: that by producing vibrations by the voice upon a disc placed in a certain position we are able to produce effects which reproduce those sounds.

Now, in order to make this plain to you, I have again called in the kind aid of Mr. Edmunds to produce before you the experiments which I had the pleasure of bringing before the Royal Institution. I have here what is called a Reiss' transmitter. At the end of this nickel-plated brass tube is a diaphragm of india-rubber, and whenever I speak into that tube the india-rubber disc vibrates. You can hear it vibrate by the two plates at the contact points coming into contact. Whenever those two plates come into contact with each other they complete the circuit of a battery which passes through the primary coil of an induction coil, and the secondary circuit of that coil passes through a vacuum tube. This vacuum tube rotates by means of a common electro-magnetic mill worked by three Groves' cells. If the lights are put down we shall see the sparks that pass through the vacuum tube, and as different notes are sounded into this transmitter these different notes will be reproduced in different figures.

You will observe that every note has its distinct figure.

THE PHONOGRAPH AND THE TELEPHONE.—In a communication to the *Comptes Rendus* M. Bouillaud discusses the question whether the phonograph repeats words on a principle similar to that of the telephone. He asserts that, as regards force, time, speed and quality, the words of phonographic origin differ entirely from those which have been uttered, which is not the case with words repeated by an echo. Touching on the telephone, [illegible] magnetic machine.

M. BOUILLAUD, the eminent [illegible] pronounced the phonograph a ventrilo the microphone a nocturnal bombsh had his doubts as to real, for at the ad 9th, Count du Moncel again exhibite condenser" and the phonograph bel Academy, leaving it to the member experiments themselves. *Engi*

THE PHONOGRAPH will henceforth be to all purchasers, without any royalty b Company, for 100 dols. (£5) or 200 dol ing to the finish of the instrument. *Sc*

To face p. 69.

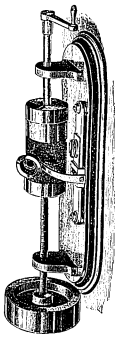

FIG. 1.

FIG. 2.

FIG. 3.

Now the evidence we have there is, that, whenever this disc is placed in front of the mouth, the sonorous vibrations issuing from the mouth, or from a musical instrument, make in that instrument a different figure.

Now in the phonograph we have a precisely similar disc—a disc identical in form and in character with the disc used in the now well-known telephone; and at the back of the disc there is a steel point which, by means of a spring, gently presses against a piece of tinfoil. Here is one of the pieces of tinfoil that is used. This tinfoil is placed around the circumference of a long cylinder, which cylinder has a thread upon it—a spiral thread—and the length in this case of this thread is about 42 feet. Now this cylinder is rotated in this particular instrument by a handle, and in order to give the cylinder a uniform rotation at the extreme end of the axle carrying the cylinder is a heavy fly-wheel. I may tell you this instrument is only the second which Mr. Edison, that wonderful genius on the other side of the Atlantic, has made. (See fig. 1.) It was brought over from America by my friend Mr. Puskas, who has brought it here, and who, as he understands the working of it better than I do, will show it you in actual operation. Now here we have all the simple conditions of a phonograph. We have a disc vibrating in response to the tones of the voice. We have a sheet of tinfoil, a yielding substance, which receives the impressions, and being highly non-elastic it retains those impressions, so that when you take up the sheet of tinfoil you will find, as far as the eye is concerned, little indentations, little rapid dots in telegraphic language, but really, as far as the eye can see, nothing but a series of these dots. (Fig. 2.) However, there is no doubt that these dots on the tinfoil follow exactly all the conditions of the sonorous vibrations expressed by the voice. Now, while I am speaking to you, vibrations enter the ear in the form of words, which strike the tympanum of the ear—an instrument identical with the mouthpiece of the phonograph. The tympanum of the ear vibrates responsively to the tones produced, which in the phonograph is imitated by the steel point at the back of the disc upon this tinfoil, so that if we take a succession of tinfoils we shall have a succession of undulations similar to

THE PHONOGRAPH AND THE TELEPHONE.—In a communication to the *Comptes Rendus* M. Boutllard discusses the question whether the phonograph reports words on a principle similar to that of the telephone. He asserts that, as regards form, tone, speed and quality, the words of phonographic origin differ notably from those which have been uttered, which is not the case with words repeated by an echo. Touching on the telephone, [illegible] magnetic machine.

M. Boutllard, the eminent presen[illegible] pronounced the phonograph a veritable microphone and a scientifical bombshell had his diaphragm at rest, for at the 2[illegible]th, Count du Moncel again exhibited Edison's condenser" and the phonograph bef[illegible] Academy, leaving it to the member experiments themselves.

THE PHONOGRAPH will henceforth be [illegible] to all purchasers, without any royalty [illegible] Company, for 100 dols. (£21) or 200 dol[illegible] ing to the finish of the instrument.

those of Mr. Barlow, only they are more minute. The marks on the paper of Mr. Barlow are very large; but these illustrations upon the tinfoil only vary a small fraction of an inch. (For magnified section, see fig. 3.)*

This impresses upon the tinfoil the marks as you see. The number of these waves or vibrations determining the note given out by the voice, the depth of the vibrations giving the loudness of the tones, and their form giving you the quality of the notes produced —whether it be the deep bass of a man's voice or the soprano of a woman's voice—whether it is a trumpet or a whistle,—every single sound imparted to that disc imparts a curve on the tinfoil, and that curve is the exact representation of the sounds. The result is, after having spoken into the cylinder you have the foil on the cylinder indented with these waves, and all you have to do to reproduce those effects is to cause those indentations on the tinfoil to go over the same course again; but in the second result, instead of being produced by the point of the disc these curves impart motion to the point, and the point imparts motion to the disc that previously vibrated; and if the motion be the same and at the same rate, and if the point goes over the same ground, tumbling into these indentations and gently riding over the hedges and ditches, the result is the disc is caused to vibrate exactly in the same way as it was caused to vibrate by the voice, and the consequence of this repetition of the vibrations is the reproduction of the same sounds.

Mr. Puskas will perhaps go to that instrument and say something to it.

[Mr. Puskas complied, and spoke as follows:—"The Phonograph presents its compliments to the company," which was repeated by the instrument with great distinctness.]

Now (continued Mr. Preece) this instrument which you have just heard is only the second of the kind ever made. We succeeded in England in getting some very careful written descriptions of it, and my friend Mr. Pidgeon, of Putney, a very able amateur mechanician, has, with the aid of his son, succeeded in producing a fac-simile of Mr. Edison's. The only difference between its construction and

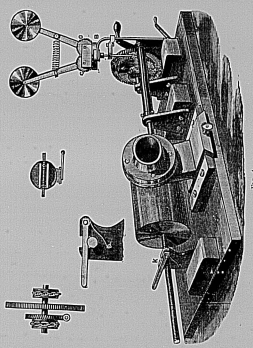

FIG. 4.

the one you have just seen is that the diaphragm into which the words are uttered is different from the one which reproduces the sounds. There are two diaphragms, and I am not sure that in abandoning his first plan Mr. Edison has made an improvement.

The great advantage, in my opinion, in having two diaphragms is that when you have a disc for receiving sonorous vibrations from the mouth you can have it set so as to be equally resilient to different voices. A strong voice or a weak voice can equally speak into it without affecting too actively the tinfoil; but that which is good for receiving sonorous vibrations is not equally good for imparting them. With a different diaphragm for receiving, it is a matter of indifference what loudness of sound is imparted. It will always reproduce the same sounds with the same amplitude. Hence you are able to make your sounding disc of lighter and more spring-like materials than your receiving disc, and you have no fear of damaging the tinfoil with loud words.

Now, Mr. Pidgeon has kindly brought his instrument here to-night. This is not to be regarded as a competitive exhibition. Here is the second instrument made by the inventor himself, and here also is the first that has been made by an amateur from a description of the inventor's own instrument. Mr. Pidgeon and his son will now exhibit that instrument to you. [Illustrated—several sentences were given and songs sung]. I am sure you will congratulate Mr. Pidgeon upon such a very excellent example of amateur mechanical skill. There is one defect in it which led Mr. Pidgeon rather to deprecate the singing of songs—that is, they come out rather out of tune. The reason is this—with the mechanical contrivance for rotation by hand it is almost impossible to produce that uniform motion which is necessary to reproduce notes in their exact pitch. Mr. Edison has endeavoured to get over that by the addition of a heavy fly-wheel; but in this instrument (pointing to another) that difficulty has been got over by the introduction of clockwork and a governor. (Fig. 4.)

Some three weeks or a month ago I had the honour of lecturing before the Royal Institution, and, the phonograph being then a greater novelty than it is now, I had been promised by Mr. Edison an instrument for exhibition, but, knowing that inventors cannot

THE PHONOGRAPH AND THE TELEPHONE.—In a communication to the *Comptes Rendus* M. Bouillaud discusses the question whether the phonograph reposts words on a principle similar to that of the telephone. He asserts that, as regards force, tone, speed and quality, the words of phonographic might differ notably from those which have been uttered, which is not the case with words repeated by an echo. Touching on the telephone, I magnetic machine.

M. BOUILLAUD, the eminent PERSEY pronounced the phonograph a ventrilo the microphone an acoustical humbug had his doubts set at rest, for at the 278, Count du Moncel again exhibite condenser" and the phonograph bef Academy, leaving it to the membe experiments themselves. Nature

THE PHONOGRAPH will henceforth be to all purchasers, without any royalty t Company, for one dollr, (£5) or 200 dol ing to the finish of the instrument. 24

always fulfil their promises as to time, I thought the better plan would be to secure the services of one of our ablest mechanicians, Mr. Stroh, to undertake the manufacture of an instrument from Mr. Edison's description. He did so, and this instrument was exhibited at the Royal Institution. It reproduced sounds in a very admirable manner, but we found the same evil—the impossibility of reproducing the exact pitch of the notes, owing to the irregular motion of the apparatus when moved by hand. So Mr. Stroh has constructed for us the apparatus you see here. It is in principle the same, but he has applied to it a weight and an ingenious governor, which secures the uniform motion that we want. It is still, however, of course, Mr. Edison's instrument. We have the disc to speak to, the cylinder with its spiral thread, the tinfoil, and everything you have seen before, but we have, in addition, that uniform motion which I hope will enable us to reproduce musical notes in a way superior to what we have yet heard.

[Mr. Spagnoletti sang into the instrument a stanza of a popular song, which was reproduced by the phonograph, and on being encored was again distinctly reproduced by the instrument. Mr. Preece also sang with similar results.] Now, Gentlemen, while Mr. Stroh is putting in another sheet of tinfoil I may mention that this inventive genius, Mr. Edison, has devoted a great deal of time to the perfecting of this instrument. His later form, instead of having this foil spread on the cylinder has it spread upon a flat disc, and the disc rotates so as to bring the foil continuously underneath the point in the form of a spiral, so that instead of having these marks upon the circumference of the cylinder they would be recorded upon the spiral curve, and he has also applied mechanical power to secure uniformity of motion. I am told that in his new instrument he has produced sound sufficiently loud to be heard at a distance of 425 feet, and he has so improved the articulation that the dictated matter was repeated at Philadelphia twelve times without mistake. The articulation is perfect, and even whispering is repeated. The sounds can be reproduced not only once, but a great many times. Take one instance. I called on Mr. Puskas immediately on his arrival at the Langham Hotel. He turned the phonograph. It said, "How do you do? what

do you think of my phonograph?" These words had been imparted to it by Mr. Edison in New York before its departure for England; they had been reproduced several times *en route* for the gratification of the passengers on board the steamer, and were again made distinctly audible to me at the Langham Hotel a fortnight after they had been originally uttered. (Applause).

The instrument itself is so simple that the dullest comprehension cannot fail to understand it.

[Mr. Spagnoletti here sang into the instrument "God Save the Queen," which was distinctly reproduced.]

Mr. PREECE remarked that there was no reason why Mr. Spagnoletti's melody should not be kept for one hundred years, say, till 1978, when the sounds would be reproduced as "God Save the Queen, sung by Mr. Spagnoletti before the Society of Telegraph Engineers in England in 1878." (Laughter.) There is just one more effect I should like to produce, though it is almost a desecration to superpose a song upon what we have just heard; nevertheless it will be worth your while to hear the effect of sounds superposed on other sounds. [This was illustrated, the two different sounds being quite distinct though simultaneous.]—Before I sit down I beg to convey my best thanks to Mr. Puskas for the loan and exhibition of Mr. Edison's instrument; to Mr. Pidgeon for bringing his clever workmanship here; and to Mr. Stroh for the exhibition of the beautiful instrument he has been kind enough to bring here and manipulate to-night.

The CHAIRMAN: It is now just our usual time for adjourning, but I am sure you would not wish to separate without an expression of your thanks to the gentlemen who have occupied us with an entertainment so agreeable as we have experienced to-night, or without conveying to Mr. Edison at New York an expression of the great pleasure which the exhibition of his wonderful instrument has afforded us. I regard this invention as an epoch in the history of sciences, and we ought not to let this occasion pass without recording a vote of thanks in return for the great pleasure we have had this evening in hearing Mr. Edison's instrument, and I hope that vote will be communicated to him by telegraph.

Carried by acclamation.

THE PHONOGRAPH AND THE TELEPHONE.—In a communication to the *Comptes Rendus* M. Bouillaud discusses the question whether the phonograph repeats words on a principle similar to that of the telm. He asserts that, as regards force, intonation, and in many the words of phonographic origin differ notably from those which have been uttered, which is not the case with words uttered by an echo. Touching on the telephone, h magnetic machine.

M. BOUILLAUD, the eminent French p announced the phonograph a ventrilo the microphone an acoustical humbu had his doubts set at rest, for at the al 7th, Count du Moncel again exhibit condenser" and the phonograph bef Academy, leaving it to the membe experiments themselves.

THE PHONOGRAPH will henceforth be to all purchasers, without any royalty t Company, for 100 dols. (£20) or 200 dol ing to the finish of the instrument.

Mr. WEAVER said he would undertake to telegraph the communication to Mr. Edison, an offer which was gladly accepted by the meeting. A cordial vote of thanks was also passed to Mr. Puskas, Mr. Falgeon, and Mr. Stroh, for the exhibition of their respective apparatus, and to Mr. Preece for his lucid description of them.

It was announced that Mr. Conrad W. Cooke had been transferred from the class of Associates to that of Members.

The Meeting then adjourned.

LE PHONOGRAPHE D'EDISON.

Après bien des expériences et des recherches, l'inventeur de cet instrument est parvenu à perfectionner sa forme au moyen à obtenir une articulation parfaite de l'enregistrer, de façon qu'elle se conserve et de reproduire les sons phonétiquement après un certain temps.

L'appareil perfectionné inscrit, non-seulement le langage et le chant, mais il répète aussi les sons des instruments de musique, le chant des oiseaux, et, les cris de tous les animaux. Il enregistre tout les sons possibles et les répète après un intervalle, avec les mêmes intentions que lorsqu'ils furent émis.

L'appareil qui produit des résultats aussi extraordinaires, est simple, en principe, quoiqu'il consiste réellement de deux instruments.

D'abord il y a le phonographe proprement dit, ou appareil à noter les sons; ensuite le mécanisme pour les reproduire, que l'inventeur appelle le "phonet." Dans le premier, les ondes sonores viennent frapper une plaque ou un diaphragme métallique placée au fond d'une chambre, pourvue d'un orifice ou embouchure. Cette plaque vibrante porte une aiguillette ou pointeau qui répond aux vibrations que reçoit la plaque et les inscrit par son série d'empreintes sur une substance convenable. Celles-ci porte donc une ligne de dépressions diverses qui forment les archives des ondes sonores, et conséquemment des sons qui ont été reçus sur la plaque du phonographe. Cette surface est ce qu'on appelle un phonogramme. Sa base est habituellement en fer blanc, ou ce qui vaut mieux une feuille de cuivre placée sur une feuille de papier, et étendue sur une surface à rainures. Ou moyen de l'électro-typie on peut alors produire une matrice ou copie en relief en fer; celle-ci peut être convertie en acier et trempée; ensuite on peut fondre des planques en des répétitions exactes du phonogramme qu'on peut multiplier à l'infini. On peut aussi obtenir des reproductions en plâtre au moyen de la pression.

Le "Phonet," ou appareil pour reproduire les sons, ressemble beaucoup au phonographe, ayant une plaque vibrante et un poinçon, mais il agit naturellement en sens inverse. Son fonctionnement, comme celui du phonographe, est simple. Le poinçon du "phonet," est ajusté de façon à tomber dans la ligne de dépressions du phonogramme, et comme celui-ci se meut dans une direction horizontale, le pointe passe dans la dentelure et tmmanet à la plaque à chaque variation de surface, des vibrations en rapport direct avec la profondeur de l'empreinte.

La plaque du "Phonet," reçoit donc les mêmes vibrations que le phonographe avait communiquées à son propre. Il s'ensuit une succession rapide d'ondes sonores qui, en passant à travers une chambre ou un entonnoir, reproduisent les sons qui avaient primitivement influencé le phonographe. Si on place un entonnoir en papier ou autre matière résonnante devant la plaque vibrante, les sons seront plus retentissants et plus clairs. L'instrument est composé d'un cylindre sur lequel la feuille de métal qui forme le phonogramme est enroulée. Pour tenir le papier métallique en place, le bords ou lisières en sont passés dans deux minuces. Le cylindre marche au moyen d'un mécanisme d'horlogo, ou par toute autre force motrice. Le mouvement longitudinal est obtenu par le moyen d'une vis. Le poinçon à la même forme que celui du phonographe, mais il est plus petit afin d'arriver au fond des dépressions sans en toucher les bords. Il est fixé sur un levier placé au-dessus de la plaque du "Phonet," et se repose sur le cylindre; son poids et celui du levier sont suffisants pour obtenir la pression nécessaire sur le phonogramme.

La Fig. 1 montre une section du phonographe et une élévation de la section du mécanisme pour roumettre la feuille métallique, enlevée à l'action du poinçon; la Fig. 2 est un plan du phonographe; *a* est le cylindre couvert à l'action du poinçon; *b* la plaque vibrante; *c* le poinçon. Il y a une ouverture formant l'entonnoir dans la chambre, et par laquelle les vibrations d'air arrivent à la plaque. Celle-ci est fixée au chassis par les bords, laissant un espace pour lui permettre de vibrer librement. Le poinçon qui est en diamant, ou autre substance résistante, est rendu sur un ressort tubulin *e*. Entre celui-ci et la plaque il y a un morceau de caoutchouc tubulaire pour amortir le coup, et empêcher les fausses vibrations. Le poinçon agit avec beaucoup plus de justesse par ce moyen, que lorsqu'il est fixé directement sur la plaque vibrante.

Le phonographe est placé sur un bras de levier *i*, sur un pivot *f* à la vis *g*, de façon qu'il peut être mû horizontalement ou verticalement, pour une raison que nous indiquerons plus loin.

On comprend maintenant que si une personne parle près de l'embouchure ou tube d'admission du phonographe, les ondes sonores se porteront sur la plaque, et la feront vibrer; le poinçon aura également agité, et si on approche une feuille de métal près de l'extrémité du poinçon, et qu'on lui imprime un mouvement horizontal, et qu'on imprime en mouvement au poinçon, le résultat sera une série de marques formant un registre de vibrations sonores.

La manière de placer la feuille qui doit recevoir l'empreinte et de lui imprimer le mouvement est comme suit :—*a* est un disque fixé sur l'arbre *d* et tournera avec lui. *f* est un chassis fixé sur le disque au moyen d'une charnière. Il y a deux rainures hélicoïdales 3, 4, dans la surface du disque et aussi les chevilles 2, 2, qui correspondent avec des orifices dans le chassis. La feuille de métal qui doit recevoir l'impression est de la même forme et de la même grandeur que le disque et ce-ci-dessus *f*; elle est percée de trous qui correspondent avec la position des chevilles 2, 2. Lorsque la feuille est placée sur le disque, on amène le chassis dessus pour la tenir en place. On peut pratiquer dans la feuille de métal une ouverture ovale, ou un peu plus grande qui reçoive occupé par la spirale 3. Les bords extérieurs de la

EDISON'S PHONOGRAPH.

Extensive experiment and research has enabled the inventor of this instrument so far to improve its construction as to give thereby very perfect articulation, to produce mechanically a record of the sons in a convenient form for preservation, and from this record to reproduce the sounds phonetically after any reasonable length of time. By this means, not only the various sounds made by the human voice in speaking and singing, but those made by various musical instruments, birds and other animals, or indeed any sound whatever, can, from a set of permanent characters, be, as it were, read off by machinery, and at any desired moment be uttered, as if by their original agent or producer.

The instrument which is capable of accomplishing these astonishing results is comparatively simple in principle, and consists essentially of two distinct instruments. First, the "Phonograph," proper, or sound-recording apparatus; and second, the mechanism for reproducing the sounds, which the inventor calls the "Phonet," in the first of these, the sound-vibrations or undulations produced in the atmosphere are brought to bear upon a metallic plate or diaphragm, placed at the back of a chamber provided with an opening, or mouthpiece. Attached to or otherwise placed in connection with this vibrating plate is a small point, which, moving in unison with the vibrations thus imparted to the plate, produces upon the surface of a suitable material that is moved along mechanically in contact with it, a series of minute impressions or indentations. The line of marks or depressions thus produced forms a permanent record of the sound-waves, and consequently of the sounds themselves, which acted on the diaphragm or phonograph-plate.

From this indented surface, or "Phonogram," as it is called, which usually consists of a strip or sheet of tinfoil, or, what is better, thin copper sometimes, a sheet of paper and stretched upon a grooved surface, a matrix or copy in relief may be made of iron by electrotype deposit, which may be converted into steel, hardened, and used for impressing sheets or rollers of metal, thereby enabling the original sound-record to be multiplied indefinitely. A plaster cast can be used for producing a copy by pressure.

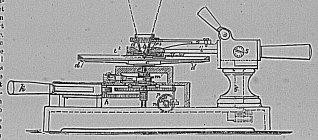

FIG. 1.

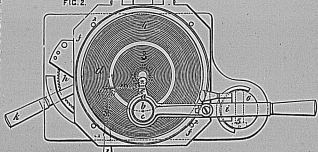

FIG. 2.

The "Phonet," or apparatus for reconverting or translating the marks produced by the phonograph (or a reproduction of them) into the corresponding and original sound-vibrations is somewhat similar in construction to the Phonograph, being provided with a vibrating diaphragm and point, but its action is, of course, reversed. The manner in which it performs its office is, like that of the latter instrument, comparatively simple. The point connected with the diaphragm is so adjusted as to fall into the line of indentations in the foil, and, as the latter is moved along beneath and in contact with it, the point passes from one indentation to another, and receives a movement corresponding to the depth of the indentations, transmitting this movement to the diaphragm, and the latter is thus thrown into a state of vibration corresponding exactly with that of the diaphragm which operated the indenting-point of the phonograph, the effect of this movement as to produce a rapid succession of air-waves, which, passing through a chamber or funnel, give rise to exactly similar sounds as those which had been originally communicated to the phonograph-plate. A funnel of paper or other resonant substance is placed in front of the diaphragm to render the sounds louder and more distinct. The instrument essentially consists of a cylinder or barrel, around which the sheet or strip of foil forming the phonogram is wrapped, the edges being held firmly by being passed into a slit. This cylinder is then rotated by clock-work or other suitable mechanism, and at the same time is moved lengthwise by the action of a screw. The vibrating point, which corresponds in shape to that of the Phonograph, but is slightly smaller, so as to follow the bottom of the depressions in the foil, without coming in contact with the sides, is attached to an arm or lever, placed above the vertical axis of the Phonet, so as to rest upon the cylinder, the weight and leverage of the arm producing the necessary pressure upon the phonogram.

Fig. 1 shows a section of the Phonograph and a sectional elevation of the mechanism for presenting the surface to be indented and Fig. 2 is a plan of the same; *a* is the body portion of the diaphragm, and *c* the indenting point. The latter is a small conical projection forming the mouth-piece, into which a person speaks, or through which opening the sound vibrations pass to act upon the diaphragm. The diaphragm—which is made of thin sheet of iron, is secured at its edges to the body, being *b* spaces between them in order to allow the diaphragm to vibrate freely. The indenting point, which consists of a diamond or other very hard substance, is mounted upon a small elastic spring arm *e*, inserted between this spring and the diaphragm a short piece of india-rubber tube is placed, to act as a damper for preventing false vibrations. By this arrangement the action is rendered much more perfect than when the point is fixed directly on the diaphragm.

The phonograph-point is mounted upon a lever arm *i* pivoted at *f* to the vertical stud *h*, so that the phonograph may be raised or lowered vertically, or moved horizontally.

It will now be understood, that if a person speaks with his mouth near the mouth-piece of the phonograph, the sound-vibrations will act upon the diaphragm and vibrate it, and will communicate to the indenting-point a similar movement, and that if a piece of metal foil or other material susceptible of being indented is placed beneath or behind the indenting-point, and caused to move regularly, the material will be indented, and form a perfect record of the sound-vibrations.

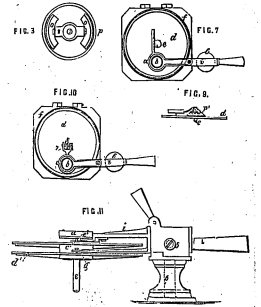
The means for sustaining the sheet to be indented, and the mechanism for moving the same, consists of the following:—*a* is disc or plate secured to and turning with the shaft *d*, and hinged to this disc is a ring-frame *f*; this disc *d* has two spiral grooves 3, 4, in its surface, and also two pins 2, 2, upon the surface of the disc, and holes at corresponding places in the

feuille sont doublés de carton au moyen de colle forte ou de gomme. Nous avons dit que la surface du disque d portait deux rainures hélicoïdales 3 et 4; la rainure 3 guide une cheville placée sur un bras g sur le phonographe et 4 guide le poignon c. Le disque et la feuille sont mis en mouvement et la rainure 3 fait occuper au poignon une position directement au dessus de la spirale 4, et l'empreinte sur la feuille de métal suivra la direction de cette dernière comme on voit dans la Fig. 2.

La deuxième sur la feuille du métal forme un registre exact des vibrations d'air reçues par la plaque. Cette feuille de métal inscrite est le phonogramme, et c'est par elle qu'on reproduit les sons. Le phonographe est emporté par l'action de la spirale 3, et se meut sur la tige verticale 6. Et en dépeignant l'extrémité des leviers f, le phonographe prend une position qui permet d'ouvrir le châssis f, et alors on peut enlever la feuille de métal du dessus le disque.

L'arbre e tourne au moyen d'un poids ou d'un ressort et de l'engrenage qui se trouve au point h, et on remonte le ressort par le mouvement alternatif de levier k et de l'action d'une roue dentée, et d'un linguet de construction ordinaire; l'axe un levier qui a une rainure à son extrémité extérieure pour recevoir le levier m, fixé au moyen d'une cheville. L'autre bout du levier m communique avec la bride d'accouplement m', et, en faisant fonctionner le levier l, l'arbre e est mis en communication ou détaché du l'engrenage h. Ainsi on peut arrêter le disque d, ou le mettre en mouvement sans déranger la force motrice.

Pour assurer l'uniformité du mouvement de l'arbre e, et surtout pour empêcher qu'il ne marche trop vite, il faut placer un régulateur ou pointe s, et ceci peut se faire comme dans les Figs. 1, 2 et 4, on peut voir des blocs de métal o, aux extrémités de bras à ressorts pertants de la traverse d'un arbre qui dérive son mouvement du point A. Ces blocs sont placés dans l'intérieur d'un cylindre immobile p, et lorsque la rapidité est trop grande, ils viennent en contact avec la surface intérieure du cylindre et la friction qui en résulte ralentit le mouvement. Dans la Fig. 6 ces bras sont attachés à un prisme. Il est bon de couvrir les surfaces qui sont les plus près du cylindre p avec du feutre ou autre étoffe qui leur permette de glisser sur la surface du cylindre tout en produisant une friction moyenne selon l'action centrifuge.



On peut remplacer la spirale 3 par un des expédients représentés dans les Figs. 6, 7, 8, 9 et 10.

Dans les Figs. 6 et 7 l'arbre e passe au dessus de la surface du disque d. Il y a une sorte d'arbre qui agit sur une embouchure fixée dans le phonographe, et à chaque révolution de l'arbre, la excentricités et excentriques exécutés aux points où la dent vient en action. Dans ces machines il faut former les spirales selon le mouvement du phonographe.

Dans la Fig. 8 une vis sans fin sur l'arbre e, agissant sur un pignon fait tourner l'arbre e', et les vis sans fin à l'autre bout de l'arbre e', agissant sur les dents qui sont autour de la base du levier f, sur la tige 6, fait avancer le phonographe graduellement. Ici, la spirale 3 est remplacée par une identique avec celle de la figure d.

Dans la Fig. 9 l'arbre e porte une fusée au point p', et une entaillure d'un bras de levier, qui est attaché au phonographe, se trouve rapportée contre cette fusée dont les spirales emportent le phonographe par degrés, et la ligne inscrite forme la même courbe que la spirale 3.

Dans la Fig. 10 les dents d'un pignon à vis fixé sur l'arbre e, agissent sur une came 7, et en forme la spirale 3.

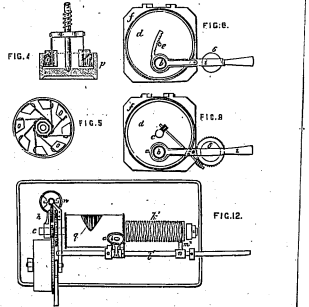
Dans la Fig. 11 la rainure hélicoïdale 3 pour la cheville g est sur un disque d' sur l'arbre e, mais elle occupe la même position relative sur ce disque d', que la rainure 4 occupe sur le disque d. Ainsi le mouvement du phonographe lui est imprimé de la rainure sur le disque d', par l'action des bras g and 6, sur le pivot vertical 6.

Au lieu de placer la feuille métallique sur le disque d, on peut en entourer un cylindre c, Fig. 12. Ce cylindre est sur un arbre e', soumis à l'action de l'engrenage h' ; l'arbre porte vis à double pas qui correspond avec une double rainure hélicoïdale dans la surface du cylindre c. Le phonographe est attaché à un arbre pivoté f', logé au moyen d'un levier pouvant alternatif au moyen de la vis k', qui agit sur le bras m', fixé sur l'arbre f'. A mesure que le phonographe marche dans une direction, les empreintes sont faites selon une spirale sur la plaque métallique sur le cylindre c. Lorsque le bras m' arrive à l'extrémité de la vis, le

ring-frame; the sheet to be indented is of a size and shape to correspond with that of the disc d and the frame f, and said sheet has holes in it, corresponding to the position of the pins 2, 2, and these holes form register-marks in placing or replacing the sheet upon the disc d, and after the sheet is so placed the ring frame f is brought down upon the sheet and holds it firmly in place. There may be a central opening in the indented sheet of a size slightly larger than the space occupied by the spiral 3, and the outer edges of the sheet are stiffened by a ring of thick paper or pasteboard caused to adhere by glue or other adhesive material. The surface of the disc d is made with two spiral grooves 3 and 4 as aforesaid; the groove 3 is a guide for a pin that is upon an arm g on the Phonograph, and the groove 4 is for the indenting-point c. As the disc and sheet are revolved, the groove 3 causes the indenting-point to occupy a position immediately over the line of the spiral 4, and the indentations will be made upon the sheet of foil in a line corresponding to that of the spiral 4, shown in Fig. 2. The indentations made in the foil are a complete record of the sound-vibrations that act upon the diaphragm b, and from this indented sheet, or "phonogram," the sounds can be reproduced. The phonograph is carried outwardly by the spiral 3, and in so doing the parts swing upon the vertical stud 6. *By depressing* the outer end of the lever f, the phonograph is raised, so that it can be swung aside from the disc d, to allow of the ring frame f being thrown back, and the "phonogram" removed from the disc.

The shaft e is revolved by a weight or spring, and gearing at h, and the spring is wound up by moving the lever k back and forth, which acts upon a ratchet and pawl of ordinary construction; l is a lever provided at its outer end with an inclined groove, in which is a pin on the lever m, and the other end of this lever m is connected with the coupler m', by moving the lever l one way or the other, the shaft e will be connected to or disconnected from the gearing h, and hence the disc d may be stopped or started without interfering with the motor.

As it is necessary that the shaft e should be revolved with uniformity, it is necessary to provide a governor 8; s, to prevent the apparatus receiving too rapidity; and this may be made as in Figs. 1, 2, and 4, in which there are metal blocks o at the ends of springs-arms from a cross-head on a shaft driven by the gearing h, these blocks swinging radially, and acting against the interior of a stationary cylinder p if the speed becomes too great, thereby checking the speed by the friction of the blocks against the cylinder. These spring-arms may be screwed at one end to a pivotable block, as shown in Fig. 5. It is preferable to cover the surfaces of the blocks o next the cylinder p with felt, or similar material, that will slide upon the interior surface of the cylinder p, but produce more or less friction, according to the centrifugal action.



The guide-spiral 3 may be dispensed with, and either of the devices shown in Figs. 6, 7, 8 [illegible]

In Figs. 6 and 7 the shaft e passes above the surface of the disc d. In the former case there is upon the shaft, contiguous to a rack-bar extending from the phonograph, hence each revolution of the shaft, the rack-bar and the phonograph will be moved the space of one tooth, consequently the lines of indentations will be parallel and concentric to the shaft e, excepting at the places where the teeth acts to move the rack-bar and the phonograph outward or inward. In this case the spiral grooves are cut to correspond to the feed.

In Fig. 8 a worm upon the shaft e acts upon a worm-pinion to revolve the shaft e', and the worm at the other end of this shaft e' acts upon teeth around the base of the lever l on the stud 6. By this device the phonograph will be moved outward gradually, and the line of indentations will be in a spiral corresponding to the continuous spiral groove 3 in the plate d.

In Fig. 9 the shaft e is made with a fusee at p', and one end of a swinging arm connected to the phonograph takes against the same. The spirals of the fusee gradually more as the disc and shaft are revolved, and the spiral-line of indentations will be similar to that made by the spiral 3.

In Fig. 10 the shaft e is provided with a screw-pinion meshing with teeth upon a cam-wheel 7. This gives the same movement to the phonograph as the spiral groove 3.

In Fig. 11 the guide-groove 3 for the arm g is upon a disc d' upon the shaft e, but the groove 3 occupies the same relative position upon the disc d' as the groove 4 does upon the disc d, so that the phonograph is moved outwardly by the groove of the disc d', swinging both the arms g and f upon the vertical pivot 6.

Instead of the sheet of metal foil being upon the disc d, it may be wrapped upon a cylinder c, Fig. 12. In this case the cylinder is upon a shaft e' revolved by the gearing at h', and upon said shaft there is a right and left hand screw at k', and there is a corresponding double-spiral groove in the surface of the cylinder c. The phonograph is carried by a swing arm on a pivoted shaft f', and said shaft is moved endwise back and forth by the screw k', acting upon the arm m' that is secured to the shaft f'. As the phonograph is moved in one direction, the line of indentations is made spirally in the foil on the cylinder c, and when the arm m' reaches

feuille sont doublés de carton au moyen de colle forte ou de gomme. Nous avons dit que la surface du disque d portait deux rainures hélicoïdales 3 et 4 ; la rainure 3 guide une chevillette placée sur un bras g sur le phonographe et il guide le poinçon c. Le disque et la feuille sont mis en mouvement et la rainure 3 fait occuper au poinçon une position directement au dessus de la spirale 4, et l'empreinte sur la feuille de métal suivra la direction de cette dernière comme on voit dans la Fig. 2.

La douzaine sur la feuille de métal forme un registre exact des vibrations d'air reçues par le phone. Cette feuille de métal inscrite est le phonogramme, et c'est par elle qu'on reproduit les sons. Le phonographe est emporté par l'action de la spirale 3, et se meut sur la tige verticale 6. Si on dispense l'extrémité des leviers i, le phonographe prend une position qui permet d'ouvrir le châssis f, et alors on peut enlever la feuille de métal du dessus le disque.

L'arbre e tourne au moyen d'un pédale ou d'un ressort et de l'engrenage qui se trouve au point A, et on remonte le ressort par le mouvement alternatif du levier a et de l'action d'une roue dentée, et d'un linguet de construction ordinaire ; l est un levier qui a une rainure k aux extrémité extérieure pour recevoir le levier m, fixé au moyen d'une cheville. L'autre bout du levier m communique avec la bride d'accouplement m', et on faisant mouvoir le levier l, l'arbre e est mis en communication ou détaché de l'engrenage A. Ainsi on peut arrêter le disque d, ou le mettre en mouvement sans déranger la force motrice.

Pour assurer l'uniformité du mouvement de l'arbre e, et surtout pour empêcher qu'il ne marche trop vite, il faut placer un régulateur au point n, et ceci peut se faire comme dans les Figs. 1, 2 et 4, on peut voir des blocs de métal o, aux extrémités de bras k remués parallèles de la traverse d'un arbre qui dérive son mouvement du point A. Ces blocs sont placés dans l'intérieur d'un cylindre immobile p, et lorsque la rapidité est trop grande, ils viennent en contact avec la surface intérieure du cylindre et la friction qui en résulte mettent le mouvement. Dans la Fig. 6 ces bras sont attachés à un pignon. Il est bon de couvrir les surfaces qui sont les plus près du cylindre p avec du feutre ou autre étoffe qui leur permette de glisser sur la surface du cylindre tout en produisant une friction moyenne selon l'action centrifuge.

FIG. 3

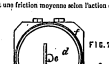


FIG. 7

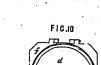

FIG. 10

FIG. 9.

FIG. 11

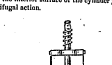

FIG. 4

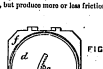

FIG. 6.

FIG. 5

FIG. 8

FIG. 12.

On peut remplacer la spirale 3 par un des expédients représentés dans les Figs. 6, 7, 8 et 9.

Dans les Figs. 6 et 7 l'arbre e passe au dessous de la surface du disque d. Il y a une dent sur l'arbre qui agit sur une crémaillère fixée dans le phonographe, et à chaque révolution de l'arbre, la crémaillière et le phonographe font un pas en avant ; les figures des dentelures seront semblables et concentriques excepté aux points où la dent vient en action. Dans ces machines il faut former les spirales selon le mouvement du phonographe.

Dans la Fig. 8 une vis sans fin sur l'arbre e, agissent sur un pignon fait tourner l'arbre e', où la vis sans fin k fixée au bout de l'arbre e', agissent sur les dents qui sont autour de la base du levier i, sur la tige h, fait avancer le phonographe graduellement. Ici, la spirale des empreintes sera identique avec celle de la plaque d.

Dans la Fig. 9 l'arbre e porte une tête ou pointe p', et une entretoise d'un bras de levier qui est attaché au phonographe, se trouve rapportée contre cette tête dont les spirales empreintes le phonographe par disque, et la ligne inscrite forme la même courbe que la spirale 3.

Dans la Fig. 10 les dents d'un pignon à vis fixé sur l'arbre e, agissent sur une roue 7, et qui forme la spirale 3.

Dans la Fig. 11 la même hélicoïdale 3 pour la chevillette g est sur un disque d' sur l'arbre f, mais elle occupe la même position relative sur ce disque d', que la rainure 4 occupe sur le disque d. Ainsi le mouvement du phonographe lui est imprimé de la rainure sur le disque d', par l'action des bras g and i, sur le pivot vertical 6.

Au lieu de placer la feuille métallique sur le disque d, on peut en entourer un cylindre p, Figs. 12. Ce cylindre est sur un arbre e', semble à l'action de l'engrenage A' ; l'arbre porte un vis à double pas qui correspond avec une double rainure hélicoïdale dans la surface du cylindre p. Le phonographe est attaché à un arbre glissant f', lequel se meut par frottement alternatif au moyen de la vis de k', qui agit sur le bras m', fixé sur l'arbre l'. A mesure que le phonographe marche deçà une direction, les empreintes sont faites selon une spirale sur la plaque métallique sur le cylindre p. Lorsque le bras m' arrive à l'extrémité de la vis, [illegible] et [illegible] la main spirally in the foil on the cylinder p, and when the arm m' reaches

ring-frame ; the sheet to be indented is of a size and shape to correspond with that of the disc d and the frame f, and said sheet has holes in it, corresponding to the position of the pins 2, 2, and these holes form register-marks in placing or replacing the sheet upon the disc d, and after the sheet is so placed the ring frame f is brought down upon the sheet and holds it firmly in place. There may be a central opening in the indented sheet of a size slightly larger than the space occupied by the spiral 3, and the outer edges of the sheet are stiffened by a ring of thick paper or pasteboard caused to adhere by glue or other adhesive material. The surface of the disc d is made with two spiral grooves 3 and 4 as aforesaid; the groove 3 is a guide for a pin that is upon an arm g on the Phonograph, and the groove 4 is for the indenting-point c. As the disc and sheet are revolved, the groove 3 causes the indenting-point to occupy a position immediately over the line of the spiral 4, and the indentations will be made upon the sheet of foil in a line corresponding to that of the spiral 4, shown in Fig. 2. The indentations made in the foil are a complete record of the sound-vibrations that acted upon the diaphragm b, and from this indented sheet, or "phonogram," the sounds can be reproduced. The phonograph is carried outwardly by the spiral 3, and in so doing the parts swing upon the vertical stud 6. By depressing the outer end of the lever i, the phonograph is raised, so that it can be swung aside from the disc d, to allow of the ring frame f being thrown back, and the "phonogram" removed from the disc.

The shaft e is revolved by a weight or spring, and gearing at A, and the spring is wound up by moving the lever k back and forth, which acts upon a ratchet and pawl of ordinary construction; l is a lever provided at its outer end with an inclined groove, in which is a pin on the lever m, and the other end of this lever m is connected with the coupler m', by moving the lever l one way or the other, the shaft e will be connected to or disconnected from the gearing A, and hence the disc d may be stopped or started without interfering with the motor.

As it is necessary that the shaft e should be revolved with uniformity, it is necessary to provide a governor at n, to prevent the apparatus revolving too rapidly; and this may be made as in Figs. 1, 3, and 4, in which there are metal blocks o at the ends of spring-arms from a cross-head on a shaft driven by the gearing A, these blocks swinging radially, and acting against the interior of a stationary cylinder p if the speed becomes too great, thereby checking the speed by the friction of the blocks against the cylinder. These spring-arms may be received at one end to a prismatic block, as shown in Fig. 5. It is preferable to cover the surface of the blocks o next the cylinder p with felt, or similar material, that will slide upon the interior surface of the cylinder p, but produce more or less friction, according to the centrifugal action.

The guide-spiral 3 may be dispensed with, and either of the devices shown in Figs. 6, 7, 8 and 9, could be [illegible]

In Figs. 6 and 7 the arbor e passes below the surface of the disc d, and has a [illegible] upon the shaft, contiguous to a rack-bar extending from the phonograph, hence each revolution of the shaft, the rack-bar and the phonograph will be moved the space of one tooth, consequently the lines of indentations will be parallel and concentric to the shaft e, excepting at the places when the teeth acts to move the rack-bar and the phonograph outward or inward. In this case the spiral grooves are cut in correspond to the feed.

In Fig. 8 a worm upon the shaft e acts upon a worm-pinion to revolve the shaft e', and the worm at the other end of this shaft e' acts upon teeth around the base of the lever i on the stud 6. By this device the phonograph will be moved outward gradually, and the line of indentations will be in a spiral corresponding to the continuous spiral groove in the plate d.

In Fig. 9 the shaft e is made with a fosse at p', and one end of a swinging arm m' is connected to the phonograph, and is taken against the same. The spirals of the fosse gradually move as the disc and shaft are revolved, and the spiral-line of indentations will be similar to that made by the spiral 3.

In Fig. 10 the shaft e is provided with a screw-pinion meshing with teeth upon a cam-wheel 7. This gives the same movement to the phonograph as the spiral groove 3.

In Fig. 11 the guide-groove 3 for the arm and pin g is upon a disc d', upon the shaft e, but the groove 3 occupies the same relative position upon the disc d' as the groove 4 does upon the disc d, so that the phonograph is moved outwardly by the groove of the disc d', swinging both the arms g and i upon the vertical pivot 6.

Instead of the sheet of metal foil being upon the disc d, it may be wrapped upon a cylinder p, as in Fig. 12. In this case the cylinder is upon a shaft e' revolved by the gearing A', and upon said shaft there is a right and left hand screw at k', and there is a similar double spiral groove in the surface of the cylinder p. The phonograph is carried by a slotted shaft f', and said shaft is traversed endwise back and forth by the screw k' acting upon a [illegible] that is secured to the shaft f'. As the phonograph is moved in one direction, the [illegible] is made spirally in the foil on the cylinder p, and when the arm m' reaches

celle dont le pas est dans le sens inverse, renverse son mouvement, et la phonographe produit une seconde spirale d'empreintes qui croise la première. Cette machine est fort utile lorsque la surface du cylindre est formée de métal galvanisé ou d'une autre matière fondamentale du phonogramme, et que l'on désire que les mots ou les sons ne soient réproduits autoestinguement, et à des intervalles marqués.

Il est préférable d'employer une mince plaque de métal a^3, comme dans les Figs. 13 et 14, dont une des extrémités est sur un pivot; la plaque étant placée dans une rainure longitudinale tracée sur la surface du cylindre g. Ce système maintient la plaque dans sa position. La surface supérieure de la plaque métallique a^3 est de niveau avec la surface du cylindre, et cette plaque porte des rainures qui correspondent avec celles du cylindre aux passant interrompues la marche du poinçon. On peut encore employer un fil à chaque extrémité du diamètre du cylindre et le tenir en place au moyen de tous qu'on peut élever ou abaisser par une came. L'expérience démontre que l'oreille en aimé par une interruption d'un huitième de pouce (0m,254).

Les appareils 1 et 14 sont semblables au No. 12, la seule différence étant que le phonographe est immobile tandis que le cylindre a un mouvement horizontal. La vis de l'arbre e^2 n'a qu'à un pas; il faut donc remettre le cylindre à sa place à la main, si on désire reproduire des sons du phonogramme, ou si on veut continuer le travail du phonographe, après qu'une nouvelle feuille métallique a remplacé celle qui vient d'être terminée. Ceci se fait aisément en levant la lame a^2, et détachant au dent de la vis k^1. L'arbre e^2 et le cylindre sont alors désengagés et peuvent se mouvoir d'un côté à l'autre.

Dans la Fig. 15 le phonographe accomplit le mouvement horizontal au lieu du cylindre g, mais comme l'arbre e^2 ne porte qu'un pas de vis, il faut remettre le phonographe à sa place après avoir désintégré le lame O^1, de la vis k^1.

Dans les Figs. 12 et 15 le phonographe peut tourner sur l'arbre l^1, pour détacher le poinçon du cylindre y afin de placer une nouvelle feuille métallique sur ce cylindre. Quand le phonographe reprend sa position on l'ajuste au moyen de la vis k.

Dans les Figs. 13 et 14 le mouvement du phonographe est horizontal au lieu d'être vertical, et l'appareil tourne sur le pivot q. La vis d'ajustage S est aussi en usage.

Si on désire opérer la répétition des sons dans l'instrument qui les a reçus, on n'a qu'à faire traverser le ligne des empreintes par le poinçon c, et ajuster un entonnoir selon les figures pointillées, qu'on voit dans la Fig. 1, pour donner de la pureté et de la force aux sons.

FIG. 13.

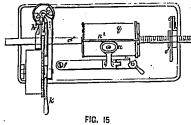

FIG. 15

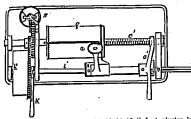

Dans les appareils 1, 2, 6, 7, 8, 9, 10, 11, 13, 14, 15, il faut ajuster le "Phonet" à la main comme nous avons déjà expliqué, afin que le poinçon c soit placé au commencement de la spirale d'enregistrement. Le poinçon c passe d'une empreinte à une autre, par un mouvement horizontal comme dans les Figs. 12 et 16, ou en fait passer la feuille métallique par le même mouvement sous le poinçon, comme dans les Figs. 1, 2, 6, 7, 8, 9, 10, 11, 13, 14.

Au lieu de la feuille métallique on peut faire usage de papier ou d'autres matières après leur avoir donné une couche de paraffine ou d'un autre hydro-carbone, de cire, de gomme ou de laque. On peut faire passer une feuille d'une de ces substances dans un bain de paraffine chauffée, et ensuite entre deux rouleaux; puis on place un papier métallique excessivement mince sur la surface obtenue, et on fait passer cette double feuille au laminoir. Si on se sert de la feuille ainsi préparée on obtient une empreinte très-nette où l'extrémité du poinçon n'est pas chargé d'huile.

Dans la Fig. 16 le poinçon c est attaché à un bras à ressort c^4, de même que dans les Figs. 1 et 2, mais il y a des longueurs de tube en caoutchouc c^5 de chaque côté de la plaque des vibrations à, pour amortir le coup et empêcher les vibrations fausses.

Dans la Fig. 17, le caoutchouc de la plaque agit contre le bout extérieur du bras c^4 pour augmenter la force du coup et diminuer la profondeur des empreintes, ce qui permet d'employer une substance plus résistante que le fer blanc.

No. 18 est une modification de l'appareil que nous venons de décrire, la pression s'appliquo ici entre le poinçon et le support du bras, de façon à augmenter la force du coup.

La Fig. 19 montre le bras c^4 en forme de levier à ressort.

La Fig. 20 représente le poinçon placé sur le milieu d'une tige à ressort fixée au deux extrémités. La tige communique avec la plaque par une corde ou autre attache.

Dans la Fig. 21 la plaque b est de forme concave au lieu d'être plate.

Dans la Fig. 22 le poinçon est fixé sur un ressort qui fait partie de la plaque vibrante.

La Fig. 23 montre un disque sur le ressort c^4 qui est placé sur le poinçon. La surface de ce disque touche presque celle de la plaque. Ce disque est agité par l'air au moment de la vibration de la plaque, car il en est de même que les deux vibrent ensemble, et que l'air ne peut passer entre eux et s'échapper aussi rapidement qu'ont lieu les vibrations.

La Fig. 24 montre une plaque dont les vibrations sont produites par l'électro-magnétisme. Dans cet exemple la plaque est en fer, et la puissance de l'aimant varie selon la force du courant électrique passant par son hélice. Cette variation est le résultat de l'action du son sur une plaque vibrante en rapport électro-magnétique.

FIG. 14.

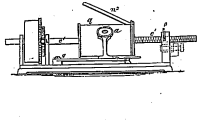

FIG. 16.

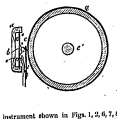

FIG. 17.

FIG. 18.

In the instrument shown in Figs. 1, 2, 6, 7, 8, 9, 10, 11, 13, 14, and 15, the phonet require to be positioned by hand, as before explained, in order that the point c may be placed at the beginning of the spiral line of indentations. The point c is caused to pass from one indentation to the next, either by the foil being moved beneath the point, as in Figs. 1, 2, 6, 7, 8, 9, 10, 11, 13, and 14, or by the point moving over the foil, as in Figs. 12 and 15.

Paper or other materials may be used instead of metal, the same being coated with paraffine or other hydrocarbons, waxes, gums, or lacs, and the sheet so prepared may itself be indented, as the material, say paper, may be made to pass through a bath of hot paraffine and thence through rollers, which give it a beautiful smooth surface. The indentation can now be made without any fear of the point sticking.

In Fig. 18, the indenting-point c is upon a spring arm c^4, as in Figs. 1 and 2, but there are short sections of rubber tube c^5 at each side of the diaphragm b to dampen the diaphragm and prevent false vibrations.

In Fig. 17, the rubber of the diaphragm acts against the outer end of the arm c^4, to increase the force and lessen the depth of indentations in the foil, and thus allow of the record being made in less yielding material than the foil.

Fig. 18 shows a modification of the last-mentioned device, the pressure being applied to the arm c^4 between the indenting-point and the support for the arm, so as to increase the depth of the indentations.

Fig. 19 shows the arm c^4 made as a lever with a spring.

Fig. 20 shows the indenting-point upon the centre of a spring bar that is firmly held at each end; the bar is connected at its centre to the diaphragm b by string or otherwise.

Fig. 21 represents the diaphragm b as of concave form instead of flat.

Fig. 22 shows the indenting-point upon a spring secured to the diaphragm.

Fig. 23 shows a disc upon the spring c^4 of the indenting point; this disc is placed quite close to the diaphragm, and is moved by the air as the diaphragm is vibrated, the disc being so close to the diaphragm that the two will vibrate together, as air cannot pass between or so close to the diaphragm that the two will vibrate together, as air cannot pass between or escape so rapidly as the vibrations take place.

Fig. 24 shows the diaphragm vibrated by electro-magnetism; in this case the diaphragm is an iron of iron, and the power of the electro-magnet will be varied by a rise and fall of the electric current passing through the helix of the electro-magnet; this rise and fall of electric tension is to be produced by the action of sound upon a diaphragm and its connections.

Dans la Fig. 25, on voit la mâchoire de faire vibrer le ressort et le poinçon par l'action directe d'un électro-aimant, sans l'intermédiaire d'une plaque, le courant électrique dans l'hélice étant varié par des vibrations sonores sur une plaque.

Dans la Fig. 26, la lame à ressort a^2, est attachée à une des extrémités d'un aimant permanent et magnétise le poinçon représenté en a^3. La feuille métallique doit être en fer. Quand le poinçon passe au dessus d'une empreinte, l'attraction est moindre que lorsqu'il passe sur surface unie, l'attraction est plus claire et plus nette, et on obtient par la grincement, causé par le frottement, du poinçon sur la feuille, attendu qu'il ne la touche pas, ces vibrations étant dûes au magnétisme.

Dans la Fig. 27, on voit deux épaisseurs en rapport avec le cylindre g; dans cet appareil le "phonet" et le "phonographe" sont séparés. Le phonographe manque de la membrane vanelle, mais la plaque "phonet" est mise en vibration par le mouvement alternatif vertical du levier e^1. Le mouvement est donné à la plaque par un levier, et le grincement sur la feuille métallique est réduit au minimum.

La Fig. 28, représente une disposition au moyen de laquelle, quatre personnes peuvent parler en même temps, le régulateur, contiendra les quatre émissions de voix en lignes parallèles, et elles seront reproduites comme venant d'une seule personne.

La Fig. 29, montre un seul phonographe, capable de recevoir les voix de trois personnes discutant ensemble. Les sons des trois voix arrivent à la plaque au moyen de tubes flexibles. Le registre se montre en quinze lignes, mais le "phonet" reproduira les trois voix.

Dans la Fig. 30, la feuille métallique est placée sur un cylindre creux, dont l'extrémité à la forme conique. Les impressions se font de la manière usuelle, mais le poinçon passe complet, tenant au travers de la feuille. Un tuou en gutta-percha est placé de façon à être toujours en face de la ligne de la dentelure; elle est en communication avec un réservoir d'air ou d'un autre fluide comprimé; chaque fois qu'une empreinte vient en face de la boue, une légère bouffée d'air passe dans le cylindre, et en entend un ne claquement. On peut faire la boue sur un ressort pour le maintenir, en face de la ligne des dentelures;

Dans la Fig. 31, il y a une grande chambre entre la plaque vibrante et l'embouchure; cet arrangement est utile, lorsque le son à remplacer vient d'une distance de quelques pieds.

La Fig. 32, montre un cylindre au moyen duquel on peut se dispenser du poinçon. Le phonographe y a la forme d'un cône. La plaque vibrante est à sa base. Une petite ouverture est percée au sommet, devant lequel passe la feuille métallique qui est placée sur le cylindre; il faut que cette feuille soit excessivement mince, afin d'être sensible à l'action des ondes sonores, concentrées par le cône.

Le Fig. 33, fait voir un "phonet," dans lequel le phonographe est inscrit sur une feuille métallique circulaire en sens fin, on peut employer comme jouet par ce qu'il est possible en outre soubriens, qui relates à l'amen. — Cette feuille peut être en acier.

La Fig. 34, qui vue vue, en perspective, qui montre un double "phonet," portant une ligne selon action, lesquels l'autre fait la même. Il faut que les billes soient en matière opposée; alors, le disque continuant sa marche dans la même direction, force un des "phonets" à vibrer en centre, puis l'autre vient en communication et en reproduira. — On peut en faire un jouet.

La Fig. 35, représente un "phonet" dans lequel le phonographe est remplacé par un jouet. — découvre, en d'une aiguille quelconque de sons, est remise sur une boîte, et se déroulant graduellement, phonographe, ainsi déroulé, fait agir le "phonet" en question. — Application facile. — Le

Dans la Fig. 36, on voit un phonographe ou "phonet," semblable à celui de la Fig. 15. Le cylindre g tourne sur son axe sans mouvement alternatif; mais le phonographe en a. Il est pourvu de quatre ressorts, a^1, a^2, a^3, a^4, et chacun d'eux est muni d'un style qui les fait agir à tour de rôle à peu près comme dans le système Wheatstone. Le style a^1 est en contact avec le cylindre, et pousse sous le ressort directeur inférieur a^2, lorsque la vis porte le bras et la phonographe vers la droite. Le ressort que ce bras est poussé sous le directeur a^2, et se dirige de la vis, et le bras est ainsi poussé sous le directeur a^3, à mesure que le mouvement en va le phonographe, et le bras est poussé sous le directeur a^4, à mesure que le mouvement se continue. Le style a^1 est ainsi ramené à son commencement du trajet. A ce point, le bras est ramené à son commencement du trajet. A ce point, le bras est poussé sous le directeur a^1, et tombe dans le jeu de la vis, celle-ci en tournant emporte le bras, et le ramène sous le directeur comme auparavant.

La Fig. 37, représente le phonographe ou le "phonet" placé sur un bras à pivot, qu'on peut placer à angle droit, sur la ligne de mouvement du phonographe. On peut obtenir des empreintes, selon une direction longitudinale ou en travers courbes, ou en lignes brisées. Le phonographe dans la Fig. 38, est semblable à celui de la Fig. 31, excepté que la chambre acoustique a une forme différente.

Dans la Fig. 39, il y a une embouchure en caoutchouc qui s'adapte à la bouche de la personne qui parle, et la plaque de vibration reçoit les ondes sonores, dans toute leur intégrité.

Dans la Fig. 40, est voit l'embouchure du phonographe avec caoutchouc et boîte irrégulières.

Dans la Fig. 41, cette embouchure est percée de plusieurs trous.

Fig. 25 shows the method of vibrating the indenting spring and point by the direct action of an electro-magnet, without the use of a diaphragm, the electric tension in the helix being varied by sound-vibrations upon a diaphragm.

Fig. 26 shows the spring arm a^2 connected to one end of a permanent magnet, so as to highly magnetize the reproducing point; in this case the foil should be of iron. When the point passes an indentation, there will be less attraction than when passing no indentation; this will give good articulation, free from the scraping noise of the point on the foil, for in this case it does not touch the foil, but is worked by magnetic attraction.

Fig. 27 represents two instruments in connection with the cylinder g; in this case the phonet and the phonograph are separate. The phonograph recevies in the usual manner, but the phonet has the diaphragm set in motion by the rise and fall of the lever e^1. In this arrangement, the diaphragm is moved by leverage and slight tension, and the scraping noise is reduced, as the foil is drawn along beneath the point e.

Fig. 28 shows an arrangement whereby four persons may speak simultaneously and have records made in separate parallel lines upon one cylinder, and the phonogram will reproduce the sounds the same as though it contained the record of but one voice.

Fig. 29 shows a single phonograph adapted to receive the voices of three persons, as in singing; the sounds made by the three voices are conveyed through flexible or other tubes to the diaphragm, and will be recorded in a single line of indentations, but, when reproduced by the phonet, the sounds uttered will correspond to the three voices.

In Fig. 30, the foil is sustained upon a hollow cylinder with a funnel-shaped end. The record is made upon the foil in the usual manner by the phonograph, excepting that holes are made entirely through the foil. A nozzle with a small opening is placed so that it will always be opposite the line of perforations as the cylinder is revolved. This nozzle is connected to a source of compressed air or other fluid, and every time a perforation comes opposite the nozzle, a puff of air passes into the cylinder, and a sound is produced upon the principle of the siren. The nozzle may be placed on a spring to keep the end of the nozzle in contact with the line of perforations.

Fig. 31 shows the phonograph as made with a large chamber between the diaphragm and the mouth-piece; this is especially useful in collecting sound when the person speaking or the sound to be recorded is made several feet from the instrument.

Fig. 32 shows a device whereby the diaphragm and cylinder may be dispensed with in the phonograph. The funnel forming the phonograph is made with a diaphragm at the larger end or mouth-piece, and a very small hole at the point of the funnel and adjacent to the foil on the cylinder g; this foil should be very thin, so that the indentations will be made by the direct action of the air-waves concentrated, by the funnel without the interposition of the indenting point.

Fig. 33 shows a phonet in which the phonogram or sound-record has been made upon an endless belt; this is a convenient arrangement for toys, as the same may be made to imitate the bark of a dog or other noise made by an animal; and this belt may be of metal or other material, and be made to run for a long period of time.

Fig. 34 is a perspective view showing a double phonet, there being a spiral line of indentations on each side of the revolving disc d, one phonet coming into action as the other finishes; in the same direction, forces the phonet from the centre outwards, so that the one finishing is connected and moved back to the centre, the other, continuing to revolve.

Fig. 35 represents a phonet in which the phonogram containing a series of indentations, spaced, circular, or otherwise, is wound upon the second roller by any suitable mechanism, and as the phonogram is thus moved, it actuates the phonet, a, b, c.

Fig. 36 shows a phonograph or phonet similar to that shown in Fig. 12; the cylinder g is set forth over the cylinder. In this instance the arm a^1, and the phonograph or phonet is movable back and passes beneath the springs a^2, a^3, a^4, a^5, and as the arm a^1 is retarded, beyond the screw b^2, and brought towards the right; as the arm a^1 moves, when the screw is carrying the arm and phonograph back to the starting point, the arm a^1 passes beneath the spring a^4, when the screw b^2 moves the shaft, phonograph, and arm, along to the place at beginning; at which place the arm a^1 drops off the end of the indented guide a^4 into the thread of the screw, and as this revolves it carries the arm along the indented guide a^4 into the thread of the screw, and at this point the phonograph or phonet again passes beneath the spring a^4 as before, and the screw or at right angles to the line of movement of the phonograph with the style, and the same line of indentations may be transferred to the wax or other material or phonogram. In of a circle.

Fig. 37 shows a phonograph similar to that shown in Fig. 15, except that the arm to which is of a different shape.

Fig. 38 shows a mouth-piece with an orifice of one inch diameter at the mouth or the place the person speaking, so that all sound waves will be confined to the chamber and diaphragm.

Fig. 40 shows the mouth-piece of the phonograph made with a flexible rubber bell or bulge.

Fig. 41 shows the mouth-piece perforated with holes.

Dans la Fig. 42, l'embouchure n'a qu'une ouverture à bords irréguliers pour renforcer les intonations sifflantes, et produire un phonogramme plus parfait.

L'embouchure 43 est en mica, avec garniture de bois.

Dans la Fig. 44, la plaque est en tissu métallique doublé de papier, au moyen d'un ciment convenable. Un cercle de papier sert à renforcer les bords du tissu.

La Fig. 45, représente une plaque en parchemin, dans le cadre b^4, tendue par des cordes et des chevilles à vis. Les cordes sont de différentes longueurs et sont soumises à des degrés différents de tension, pour renforcer ou affaiblir certains sons.

La Fig. 46, montre une embouchure pour le "phonet," imitant la forme de la bouche humaine.

Dans la Fig. 47, la chambre et la plaque sont de forme triangulaire.

La Fig. 48, représente trois cylindres creux unis d'un phonographe ou d'un "phonet," pour reproduire des trios de voix ou d'instruments.

La Fig. 49, "est un "phonet" de forme globulaire, avec ouverture en pavillon, possédant deux plaques de vibration 15 16, dont les plans coupent celui du tube à angle droit, de façon à former une chambre à air. Il y a une troisième chambre f, qui reçoit sa vibration du polygone reproducteur e, et qui, en relation l'un de la chambre, fait vibrer les plaques 15 et 16; celles-ci produisent des ondes et les sons, se confondant, sortent des deux pavillons, avec augmentation de volume et de sonorité.

La Fig. 50, représente une disposition, au moyen de laquelle on peut faire des empreintes profondes dans la feuille métallique. On emploie deux plaques, la première b^5, reçoit les ondes sonores; en même temps, elle entraîne une soupape b^6 placée dans un conduit qui communique avec un réservoir d'air ou d'un fluide comprimé; cette soupape, agissant sous l'influence des vibrations de la plaque b^5, y met à plus ou moins d'air s'arriver à la plaque b^4. Les deux plaques, accomplissent donc le même nombre de vibrations dans le même espace de temps, mais celles de b^4 étant renforcées par celles de b^5, les empreintes seront plus profondes dans la feuille métallique.

Les Figs. 51 et 52, représentent une disposition pour augmenter le volume et la sonorité des sons, reproduit par le "phonet." Les vibrations de la plaque b^4, sont transmises à la plaque b^5, au moyen d'un tube, indiqué par les lignes ponctillées dans la Fig. 51; celle-ci contrôle la soupape b^6, d'un conduit qui communique avec un réservoir d'air ou d'autre fluide comprimé. A mesure que l'air s'échappe il passe dans le pavillon du tube et produit des sons claires et distincts, reproduits des sons obtenus par l'un des "phonets" que nous avons déjà décrits.

On peut employer cet appareil, pour renforcer l'émission de voix qui a servi à faire vibrer la plaque b^4, qui a son tour a reglé les ondes sonores s'échappant de la valve b^6, et passant dans le pavillon.

La Fig. 53, représente l'instrument enfermés dans une chambre. Par ce moyen, presque toutes les vibrations atteignent la plaque du vibration.

Les chaînes 54 et 55, montrent clairement les mouvements des libres, en parlant, pouvant être reproduits. Un levier, communiquant avec la plaque, porte le polygone e. Fig. 55, la personne qui parle, prend l'extrémité de ce levier dans la bouche, et le mouvement simple des libres règle la dentelure de la feuille de métal.

Dans la Fig. 54, nous présentons un appareil semblable.

En, le "phonet" placé dans une boîte, communique avec un manche au moyen de levier et, quand on fait agir l'appareil, les libres se mettent en mouvement, et en semblant de vie et d'intention remarquable à rien, tout le temps que les vibrations sont transmises du phonographe au "phonet."

Les Figs. 56, représente un jouet, nommé "phonet," la bande métallique 56, est fixée d'un bout, sur un cylindre sur lequel elle est enroulée. En tirant la bande, elle se déroule, et son mode d'application s'enroule sur l'autre des cylindres, et en laisse aller la bande, l'élastique fait tourner le cylindre, et les sons se reproduisent dans le "phonet," au moyen du phonogramme, qui agit sur un polygone et sur une plaque a. On règle le mouvement de l'arbre par l'écrou b, le filet de la pignon 58.

Dans la Fig. 57, le cylindre qui porte la bande, est pourvu de chevilles qui passent dans des trous sur les côtés du phonogramme; ce qui donne un mouvement très-régulier.

Dans la Fig. 58, le cylindre est à roberts sur diriger la feuille métallique.

Fig. 42 shows but one opening in the mouth-piece; the edges of this are irregular. These irregular edges reinforce the hissing sounds, and cause a more perfect phonogram to be produced.

Fig. 43 represents a mouth-piece of mica, with a central opening protected at its edge by a wooden ring.

In Fig. 44, the diaphragm b is of wire gauze with a backing of paper connected to it by any suitable cement, and there is a ring of stiff paper at the edges of the gauze disc to strengthen it.

Fig. 45 represents a diaphragm b of parchment or similar material stretched tightly within the frame b^4 by cords and screws. The cords may be of different lengths and tension, and exposed to and relieve certain sounds.

Fig. 46 shows a mouth-piece for the phonet made in imitation of the human mouth.

Fig. 47 represents the body portion of the phonograph or phonet made triangular, and the diaphragm is of corresponding shape.

Fig. 48 represents three cylinders, each provided with a phonograph or phonet; this is useful in recalling and reproducing three-part singing or music.

Fig. 49 represents a phonet made as a tube, with flaring or trumpet-shaped ends, and with two diaphragms 15, 16, placed crosswise of the tube so as to form an air chamber. There is a third diaphragm f, which is vibrated by the movement of the reproducing-point e, and this diaphragm gives motion to the air in the chamber, and vibrates the diaphragms 15, 16, which latter produce air-waves, and the sounds issuing from the two trumpet-shaped ends will blend and increase the volume of sound.

Fig. 50 represents a device whereby deep indentations are made in the metal foil. Two diaphragms are employed, the first, b^5, is vibrated by the sound vibrations, and controls a valve b^6 in a tube connected with a source of compressed air; this valve b allows more or less air to pass to the diaphragm b, according to the vibration of the diaphragm b^5, hence the diaphragm b will vibrate in harmony with the diaphragm b^5, but it will be acted upon by greater force, and consequently the indentation will be deeper in the foil than if the diaphragm b was acted upon simply by the sound-vibrations of the voice.

Figs. 51 and 52 represent a device that may be used with a phonet to increase the loudness of the sounds reproduced. The sound-vibrations from the phonet are conducted by a tube shown by dotted lines in Fig. 51, to the diaphragm b^5 that controls a valve b^6 in a tube connected with a reservoir of air or other fluid under pressure, and the air as it escapes by the control with a reservoir of air or other fluid under pressure, and the air as it escapes by the control valve passes into the trumpet-shaped end of the tube, and produces sounds that are very loud and clear, and are a reproduction of the sounds resulting from the use of one of the phonets before described.

This same apparatus may be used to reproduce with louder attainment a person's voice, the sound from the voice being used to vibrate the diaphragm b^4, and thereby regulate the air-wave escaping from the valve b^6 into the trumpet.

Fig. 53 shows the speaker's head within a box or case; in this instance nearly all the sound-vibrations are upon the diaphragm.

Figs. 54 and 55 illustrate how the movements of the lips in speaking may be recorded and reproduced. In this instance, a lever applied to the diaphragm carries the indenting-point e.

Fig. 55, and the end of this lever is placed in the mouth of the speaker, and the movement of the lips produces the indentations in the foil.

A similar apparatus shown in Fig. 54 within a case is connected to the movable lips of a figure which can be given motion upon the lever, reproduce accurately all the movements made music, while being examined upon the lever, reproduce accurately all the movements made music, while being examined upon the lever, reproduce accurately all the movements made by the figure during vibrations. By this means, a remarkable semblance of vitality is obtained while the sound-vibrations are given by the phonograph to the phonet.

Fig. 56 represents a toy phonet in which the phonogram-strip 56 is secured at one end to a cylinder upon which it is wound. By pulling upon the strip it is unwound, and a rubber cord cylinder upon which it is wound. By pulling upon the strip it is unwound, and a rubber cord applied to the shaft of the cylinder. When the band is removed from the indented 57 it wound upon the shaft and winds up the phonogram upon the cylinder, and the strip, the rubber cord rotates the shaft and winds up the phonogram upon the cylinder, and the strip, the rubber cord rotates the shaft and winds up the phonogram upon the cylinder, and sounds are reproduced in the phonet by the phonogram acting upon a point and diaphragm a. The movement of the shaft is regulated by the fan, vane, and pinion 58.

In Fig. 57, the cylinder for moving the phonogram-strip is shown as provided with pins that enter holes in the edges of the strip; this causes the strip to be fed along very regularly.

In Fig. 58, the cylinder with pins is shown as made with bands to set as guides for the strip.

Le Fig. 59 montre un moyen d'agrandir les empreintes. Cet instrument porte deux cylindres dont l'un a^1, marche plus rapidement que l'autre a^2, un levier 40 sur un pivot 41, porte un pointeau 42 pour chaque cylindre. Une des pointes suit la ligne des empreintes sur le cylindre a^1, et l'autre en fait de même sur le cylindre a^2. Comme celui-ci tourne plus vite, les impressions sont plus longues, et aussi plus profondes, comme ce pointeau est à l'extrémité du levier.

Dans la Fig. 60, un des cylindres 42 est en métal trempé, et la dentelure est en relief. Il est placé de façon à pouvoir graver la phonogramme sur la surface d'un cylindre 43 en métal doux. On emploie une vis, ou parfois d'autres moyens, pour obtenir la pression nécessaire.

La Fig. 61 représente un rouleau 42 en métal dur, avec la dentelure en relief, disposé de façon à faire denteler le phonogramme dans le rouleau 43, de métal doux, lequel est pressé contre le rouleau 42 avec l'aide d'une vis ou par tout autre moyen.

Le cylindre portant une matière hélicoïdale sur sa surface, peut être fabriqué en plaquant le moule qu'on voit dans la Fig. 62 autour d'un rouleau ou autre, et en remplissant l'espace entre le rouleau et le moule de plâtre, ou avec une matière convenable. Le moule est en métal et porte un filet en spirale. Il est composé de deux pièces reliées entre elles par une charnière, afin qu'on puisse le détacher facilement, lorsque le plâtre est sec. Que ce soit pour amusement ou comme étude, le phonographe peut devenir d'un usage très-étendu. Le cylindre rotatoire que nous présentons dans la 63e figure, porte des rangs d'un, pointes représentant les lettres de l'alphabet. Il a en outre un rang de clefs qui portent les lettres correspondantes; on peut employer ce cylindre pour enseigner l'alphabet, des phrases, des discours. On peut tout apprendre du "phonet" sans se servir de la vue.

On peut appliquer des cylindres et des roues à phonogrammes aux horloges et elles disent l'heure à haute voix et donnent d'autres signaux. Au moyen de phonogrammes et de "phonets" d'un mécanisme simple, on peut construire des jouets qui reproduisent fidèlement du rire, le chant des oiseaux, le miaulement du chat, le hennissement du cheval, le ronflement du lion, et tous les autres cris des animaux. On peut obtenir la répétition de tous les sons par un moyen automatique qui remonte le poignet au commencement de chaque phrase.

Le régulateur 64 dans la Fig. 64 est le poids d'un pendule attaché à l'extrémité inférieure d'une tige ayant un joint universel 65, et le bout supérieur est attaché à une manivelle 66 qui reçoit son mouvement de l'engrenage. Avec augmentation de rapidité le poids décrit un cercle d'un plus grand diamètre et alors la résistance devient plus grande.

On peut remplacer le joint par un ressort, Fig. 65.

Dans la Fig. 66 on peut voir un aimant 67 sur la manivelle qui sert à faire tourner les pendules par l'attraction qu'il exerce sur une armature à l'extrémité supérieure de la tige, ce qui évite la friction qui provient du contact des tiges du pendule sur le manivelle.

Dans la Fig. 67 la plaque 6 communique avec deux soupapes dans un conduit 68 lequel a trois lumières. L'une correspond avec un réservoir d'air comprimé, les deux autres 70 et 71 sont en communication avec une chambre 72 sur les côtés opposés d'une plaque de membre à faire vibrer celle-ci en harmonie avec la plaque b^4, et produire un son d'un plus grand volume.

FIG. 56 FIG. 57 FIG. 58 FIG. 59

FIG. 60 FIG. 61 FIG. 62

FIG. 63 FIG. 64

FIG. 65

FIG. 67 FIG. 66

Fig. 59 shows a re-indenting device for amplifying or increasing the size of the indentations. There are two rollers, one of which a^1 travels faster than the other a^2, and there is a lever 40 pivoted at 41, and provided with a point 42 for each cylinder. One point follows the indentations in the cylinder a^1, and the other rests upon a^2, and as this travels the fastest, the indentations made thereon will be longer and also deeper, by the point being at the outer end of the lever.

In Fig. 60, one roller 42 of the pair is made of hardened metal with the sound-record in relief. This is obtained by electrotype or other process from an iron foil or other metal phonogram, and this roller is used to indent strips or sheets of foil or rollers to produce copies that can be used with the phonet.

Fig. 61 represents a roller 42 of hardened metal with the record in relief, and arranged so as to knurl or indent the phonogram in a roller 43 of soft metal that is to be pressed against the roller 42 by a screw or other suitable means.

The cylinder having a spiral grooves in its surface may be made by placing the mould shown in Fig. 62 around a cylinder or shaft, and filling the space between the cylinder and mould with plaster of Paris or other suitable material. The mould is of metal with a screw or spiral rib projecting therefrom, and it is made in two parts, and hinged, so that it can easily be removed when the plaster of Paris is dry.

For amusement or instruction, the Phonograph is capable of extended use; for instance, a revolving cylinder, see Fig. 63, containing rows of indentations representing the letters of the alphabet, and provided with keys containing corresponding letters, can be used in teaching the alphabet, and sentences, speeches, and other matter can be spoken by the Phonet, and repeated by the learner without the eyesight being called into use.

Clocks may be provided with phonogram cylinders or wheels, to call off the hours, to give alarms, &c.

By means of phonograms, and phonets connected with simple mechanism, toy animals may be constructed capable of reproducing a bird's song, a cock's crow, a dog's bark, a cat's mew, a horse's neigh, a lion's roar, or any other sound. The repetition of such sounds can be produced by the phonet-cylinder being moved automatically, so as to bring the point to the commencement of the phonogram.

The governor to regulate the speed of the instrument may be made of a pendulum weight 64, see Fig. 64, hung at the lower end of a rod that is provided with a universal joint at 65, and the upper end of the rod is moved around by a crank 66 that is revolved by the train of gearing. As the speed increases, the weight will describe a circle of larger diameter, and thereby increase the resistance.

The universal joint may be displaced by a spring wire, Fig. 65, that allows of the movement.

A magnet 67 upon the crank arm 66, Fig. 66, may be used to revolve the pendulum by attracting an armature at the upper end of the pendulum-rod, and thereby avoid the friction resulting from the contact of the surfaces of the pendulum-rod with the crank.

In Fig. 67, the diaphragm b is represented as connected to a pair of delicate piston-valve, within a tube 68 that has three ports; one, 69, is connected to a reservoir of compressed air the others, 70 and 71, are connected to a chamber 72 at opposite sides of a diaphragm, so as to vibrate the latter in harmony with the diaphragm. Then there will be greater amplitude given to the same by the pressure of the air, and by a connection to the phonet-diaphragm b^4, the sound produced will be greatly increased.

REVUE COMMERCIALE.

Des nouvelles que nous recevons tendent à prouver que, quoique la position commerciale s'améliore, il y a des entraves décourageantes. La faillite d'une bonne affaire quelquefois comme la Cornish Bank, ajoutée aux désastres financiers qui l'ont précédé influe beaucoup sur les cours des marchés.

Il y a un autre élément auquel on a récemment eu recours qui nuit considérablement à la spéculation saine. Nous voulons parler de rumeurs sans fondement, mais qui circulent partout, des crises commerciales prochaines et également des complications politiques. Nous pourrions obtenir d'autres informations à ce sujet, mais jusqu'ici il est certain que les nouvelles que l'on colporte si activement ne sont que des alarmes pour favoriser les fabriques accommodantes. Il est à déplorer que pendant la crise commerciale actuelle, des spéculations aient principes profitent en augmentant la méfiance.

A mesure que les comptes rendus de l'année passée se complètent, on voit dans certains cas que l'état des affaires n'a pas été aussi insalubre qu'on l'a annoncé tant de fois. La quantité totale de coton en magasin a été réduit à 62,000 tonnes contre 63,621 tonnes de l'année passée. Les stocks de fer sont très-grands, et on y fait encore que peu d'affaires, mais les acheteurs ne seront pas toujours inactifs.

Il y a longtemps qu'on a commencé une année en faisant des réductions de salaires dans tant d'industries, on peut dire qu'il y a une réduction générale, mais ceux qui sont les plus atteints sont les ouvriers des usines de fer. Dans les industries plus légères telles que la coutellerie, la taillie des limes, la fabrique des outils tranchants et autres, la situation des ouvriers est affectée par les petites journées que leur font faire les patrons. Il reconnu d'y avoir des mal entendus dans les diverses branches de l'industrie métallurgique, parce que les manufacturiers veulent remettre la journée à dix heures de travail comme autrefois, ou ont au moins de faire plus d'heures pour le même salaire. Il semble de l'intérêt de tous d'arriver à un compromis, car pendant la crise actuelle il est nécessaire que les ouvriers fassent quelques concessions.

Dans le cas de grèves ou de fermetures de fabriques on a recours à la main d'œuvre étrangère, et à des frais inutiles, qu'il vaut mieux éviter en contribuant dans la situation difficile dans laquelle nous nous trouvons. La grève des employés de chemin de fer du Midland est un autre exemple de ces disputes regrettables, qui dans l'intérêt de tous il est mieux vaux éviter en arrivant à un mieux, ce qui était des plus faciles, vu la peu d'importance des points, on aurait épargné ainsi bien des pertes ainsi que les désagréments aux transports de minéraux.

L'industrie de la construction des navires est très-active, et les ouvriers de l'industrie de construction de Cleveland, de Stockton et d'Hartlepool, n'éprouvent pas aux réductions de

TRADE REPORT.

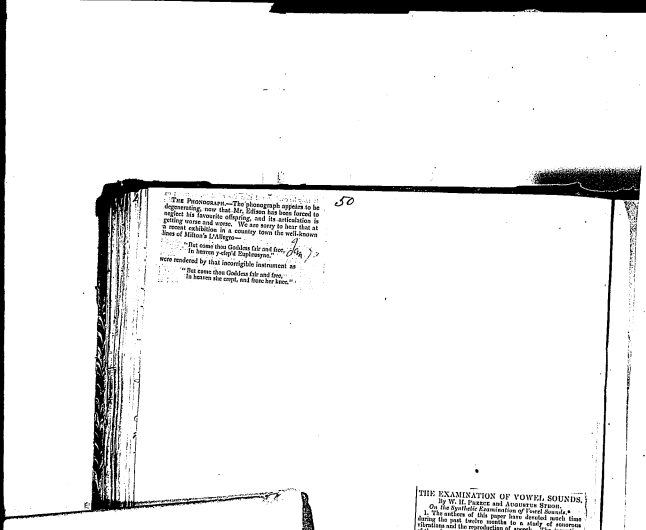
Advices received contain a considerable amount of material, all tending to prove that although in certain respects the trade prospect is improving, there are disturbing elements introduced which make the position a discouraging one. The failure of a good business like the Cornish Bank, regarded with the financial disasters which preceded it, weaken the markets immensely.

There is another element which lately has been introduced with most-effect on sound speculation. We allude to the unfounded, but widely-circulated, rumours of impending financial, or, in other cases, political difficulties. There may be further revelations of the kind, but certain it is that those now circulated so industriously are merely fictions invented for the sake of carrying on questionable transactions. It is to be deplored that in the present unsatisfactory condition of affairs, unprincipled speculators should be able to spread fresh mischief and make a profit by so doing.

As the returns for the past year gradually arrive at completion, it is seen that in some notable respects the condition of trade has been less inanimate than at time reported. The aggregate stock of copper is reduced to 62,000 tons, as against 63,621 tons twelve months previous. The stocks of pig iron are undoubtedly large, and the trade is still devoid of activity, but consumers are not likely to remain long inoperative. Probably, as soon as the evident prices have touched the lowest point, there will be a resumption of purchasing.

Seldom has a year opened with so many reductions in wages. It may almost be said that wages are being generally reduced, but the principal sufferers are still ironworkers.

In many of the lighter trades, such as cutlery, file cutting, edge tool makers, and kindred industries, the men suffer from the short time for which employers can find them work. The arrangements of disturbances in the engineering trade because employers deem it necessary to return to the ten hours system, or, at all events, to work extra time for the old rate of wages. It will be for more to the interest of all parties concerned if a compromise is arrived at, as the event of a general strike or lock-out, and a recourse to foreign labour importation to the amount, of needless expense and annoyance will be entailed which but letter be avoided. Another example of an unfortunate dispute which, for public convenience and the interest those interested, had far better have been avoided by means of a mutually agreeable arrangement, which, considering the small issue at stake, might surely have been arrived at within half the loss attendant on the strike and the delay to mineral traffic.



THE PHONOGRAPH.—The phonograph appears to be degenerating, now that Mr. Edison has been forced to neglect his favourite offspring, and its articulation is getting worse and worse. We are sorry to hear that at a recent exhibition in this country two the well-known lines of Milton's *L'Allegro*,

"But come thou Goddess fair and free,
In heaven ycleyd Euphrosyne,"

were rendered by that incorrigible instrument as

"But come thou Goddess fale and free,
In heaven ale cupd, and thurc her name."

THE EXAMINATION OF VOWEL SOUNDS.

By Professor W. HENRY and Augustus Stroh.

*On the Synthetic Examination of Vowel Sounds.**

1. The authors of this paper have described, more than three years ago, a method of analysing such thin curves as those of the phonograph, and of reconstructing them by the vibrating discs of the phonograph. This invention has proved a great stimulus to this study. Researches have been carried on in the same field, and many of the facts elicited by the authors have been anticipated by others who have been able to command more extensive study of the subject. Nevertheless, the method of inquiry, the apparatus employed, and the results elicited by the authors, appear to us to be sufficient novelty to justify their being brought before the Royal Society.

2. The curves traced by the vibrating discs of the phonograph are useful, whether examined synchronously or reproduced by a species of phonograph, were soon found to be insufficiently delicate to give the proper shades of sound, and to fail to indicate the true curve of the articulation in all cases. This is shown by the imperfect articulation still given by the phonograph itself; the merging of the sharp consonants into one another, and the absence of all the delicate and personal of the "noises" of speech. The phonograph is by no means very successful speaker, and it requires the aid of much imagination and considerable guessing to follow its representations of articulate speech. Its wonderful perfection, but it fails to reproduce many of the "noises" of which speech is so largely composed. The telephone is also deficient in this respect, though to a much less degree.

3. The first object of the authors was to find a disc which should vibrate to the least shades of successive vibrations, and which would be free from the peculiarities characteristic and "personal" portials which are nearly inseparable from all vibrating discs, and which interfere with the accurate, delicate, and indistinguishable experiments, on almost all known forms. After a long search, a stretched membrane of thin india rubber rendered rigid by a thin film of paper, was found to give the best effects. Such a disc was supplied to the telephone and the phonograph with fair success, and was attached as a receiver in Fig. 1 (see page 200) was then constructed to record its vibrations. To the centre of the membrane was attached a very similar to that in Fig. 1, which was placed to act as a receiver for the phonograph, was attached an extremely fine glass tube, and fixed acted as a pen. The ink employed was either ink, and lines drawn through the pen by the very slight friction exercised between the point and the paper. The paper p on which the curves were to be traced was then fixed bend frequently and for this purpose was attached to a small drawer under the pen by mechanism similar to that used in the Wheatstone automatic telegraph apparatus. A speed which could be carried at will from 1 in. to 60 in. per second.

4. In this way curves were obtained illustrating the successive vibrations due to the tones of speech, but their form was not so perfect as could have been wished, due to the imperfection of the disc, as well as, perhaps, to the friction of the pen failing to indicate the higher upper partials. Now at a slow speed, this instrument records the variations of air pressure perfectly, but at a rate at a sufficiently correct speed, and numerous vibrations. It thus combines the functions of Barlow's logic and of Leon Scott's phonautograph.

5. It is intended in this paper to confine our observations to these fundamental and normally sounds, a graphic representation of which, drawn by the new phonautograph, is exhibited.

6. Helmholtz's theory of vowel sounds is this. Vowels are compound musical tones, or resultant sounds, formed by the superposition of certain consecutive or simple tones called partials, the first partial, which determines the pitch of the whole, being the gravest, and the others the upper partials. The partials depend upon the reinforcements due to the cavity of the mouth, and the pitch corresponds to the cavity of the mouth, or on Q and depend therefore of the particular shape, or form, or arrangement of the particles about, but on both. The partials are consequently produced by resonance. It must recognise the kind of vowel sound, the reinforcements, and therefore it determines the different vowels. This theory has been partly confirmed by Mr. Hermann Klingling Jenkin and Ewing, by an analytical examination of phonographic tracings, fully described by them in a paper read before the Royal Society of Edinburgh.

7. The principal vowel sounds are:

A, as in	...	...	...	path
E	...	...	...	bay
I	...	...	...	fee
O	...	...	...	so
OO	...	...	...	soon
U	...	...	...	good

There are several others which are modifications of these five, such as in gull; a as in hall; ow as in how, &c. The diphthongs are:

I which is compounded of ah and o,			
A	...	...	o and oo.
O	...	...	oo and e.

8. The cavity of the mouth changes during the articulation of these diphthongs—it remains constant during the production of a vowel. It is thought that the inference of the first mentioned of these facts is allowed by the examination of the vowel curves, and that of the second, that in addition to the influence of the cavity of the mouth, reinforcements must be made for the increment of the pitch of the successive vibrations, as well as for the variation of air pressure at the commencement and completion of the vowel. Helmholtz has acknowledged the existence of these reinforcements in consonants and compound tones generally, but has not considered them in vowel sounds. The curves show what an essential feature they bear on vowel sounds.

9. Variance in which vowel sounds blend into each other is strikingly shown in the way in which different pronunciations of different words. Thus, what Londoners would call *cart* is Lancashire *aun calls sartiart*; a Londoner says *Marlborough*, a Yorkshireman says *Marrlebrer*, a Scotchman *Marlebrer*. Londoners often pronounced *Asher*, We need not, however, examine these variations in order to recover the existing blending of vowel sounds; it is found in inhabitants of the same district to a greater or less extent. Thus, for example, the word *Manchester*, *Lancheste* after *man Marlebrer*, *Manchester*, or *Marrchester*. In every case which the sound is considered, this change of vowel sound, due to dialect, is simply due to the shifting or lowering of the upper partials.

10. The order of the principal vowels, which is given above, does not follow any theoretical principle. It appears that a better order to follow would be one dependent on the pitch of the partials as given by Helmholtz.

1.	...	...	...	oo
2.	...	...	...	o } ah—(part).
3.	...	...	...	aw—(law).
4.	...	...	...	a } a—(hat).

All the subsidiary vowels, such as ow, ar, &, take up intermediate positions in this scale, so that, in fact, we may say that there is a vowel spectrum, in which the different sounds merge into each other by almost indistinguishable gradations, and hence, probably, the difficulties in distinguishing vowel sounds.

11. In the following investigation, a method opposite to that of Helmholtz has been pursued, and fixing has been adopted, i.e., the premises have been studied by the method of synthesis. It has been assumed that vowel sounds are compound of a prime sound and certain upper partials, and the number of these partials has, for convenience, been fixed at eight, although there are many more. Let these be here taken, as those were, the 10th, 12th, and 15th. Now, since each partial is represented by a simple harmonic curve, if we assume the pitch of a note to be constant, then it would be possible, by means of a tuning-fork, to sound a note and vary each partial in phase and in amplitude. For this purpose an instrument was constructed, which we call the "synthetic curve machine." It which a number of tuning-forks, A, B, C, D, E, F, G, H, &c. (Figs. 2 and 3, page 202) are mounted on a heavy cast-iron frame, A, B, C, &c., board, so that they will vibrate together and the numbers of their teeth are so calculated that distinct multiples of the speed of the wheel A will make two, C three, F four, H five, K six, G seven, H eight revolutions, and so on. The wheel A, as its peripheral axle, a small crank, by means of which the whole system of wheels can be rotated. On the same axle with A is fixed a wheel D, and on the wheel C, which, by means of a train of wheels, gives motion to a sliding table E. Each head of the pins on which the tuning-forks vibrate, has, in its centre, a small slit or hollow, in which rest the pointed ends of eight steel rods (one of which D only is represented in Fig. 6), held in position by eight springs k. To the rod on the wheel A is attached, over the forks, one end of a silken thread F, passing over its pulley, and the other end being attached to the rod on the wheel C, which also works C and D, E and F, G and H, and so on. The four rollers N are mounted on the lever V, which slightly inclined, so that the rollers N are pivoted at p, and by means of the silken lever P. This lever is pivoted at p, and by means of a silken thread to the lower end of the lever P is pivoted another lever W, which is better and a small counterbalancing suitable ink. On the table E is placed a glass pen G containing coloured glass, and a half sheet of paper or the sheet of the eight wheels has on the paper a very small circle, and the pen when the pulses of the rods F cause the curves. Whatever be the rate of speed, the tuning-forks will be in the same relative position, and the curves will be identical. If, however, two or more rods be placed on the faces of the wheels, then the pen will trace a curve compounded of the sum of the several simple curves. In order to increase or decrease the amplitude of the vibrations, each rod is placed further from, or nearer to the centre of the wheels. Difference of phase is obtained by shifting the position of the pulleys on the wheels, K, L, M, have been fitted, making in additional multiples, respectively, to one turn of the wheel A, and that they can be removed for the use of three smaller wheels, S, T, and U.

12. Besides assuming the pitch to be constant, it has been assumed that each series of the five partial, to naturalness, equal loudness of sound, must diminish somewhat in the following order. Thus the

First picture is	the amplitude of the prime.	
Second	"	"
Third	"	"
Fourth	"	"

The intermediate notes, such as the third and the fifth, increase in intermediate ratio.

13. The synthetic machine enables us to form synthetically all the curves produced by vowel tones, and to show how these tones are composed of their several partials.

14. Complex curves, such as those which can be produced by simple harmonic curves, and compound tones by the superposition of various orders of several simple tones.

The following figure (Fig. 5) shows the simple harmonic curves, a, b, c, d, and the resultant curves, e, f, g, h, which curves formed by different components. In this way curves have been reconstructed as shown in Fig. 6, representing the vowel sounds heard on Helmholtz's theory, as indicated by Mr. Ellis in a Lecture statement, at page 181 of his translation of Helmholtz's work.

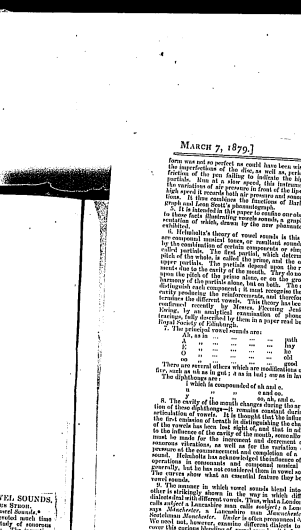


FIG. 5.

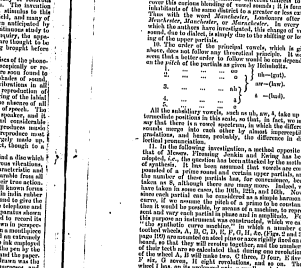

FIG. 6.

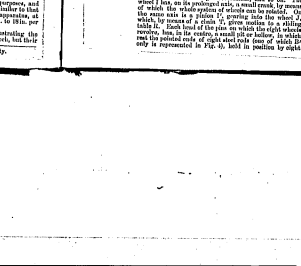

FIG. 7.

15. (It is worth remarking parenthetically, that one interesting fact arising from the operation of this machine was that curves could be so constructed as to give a stereoscopic effect. One curve was drawn simply, and the other drawn in the same line—at the proper distance from it to represent the eye—and each compound, by the addition of a partial of one amplitude. The result of the combination by the eye in a stereoscope of these two curves, was to produce a perspective effect. Thus, when certain curves were drawn which included a certain amount of such stereoscopic effects in a manner which would be out of place here. This has no bearing whatever on the present question, and is only adduced as a scientific toy arising out of the inquiry.)

16. Having thus studied the formation of vowel sounds, and having a means to reproduce the compound curves which gradually represent the articulations of speech, it remained to examine the latter themselves, the analysis of which is the object of the present paper. This we shall attempt in a future paper.

Since vowels are produced by a prime and its upper partials, and as the upper partials vibrate as rapidly in amplitude, the idea arose that these vowels might be produced by sounding a prime and one of its upper partials. This was done by means of an electro-magnet E, Fig. 1, page 202, which was made sensitive A with a microfile spring D, attached to it in such a way that the vibrations of the armature, by varying the length, could also be adjusted to any particular partial.

The result was certain was to roughly reproduce the principal vowel sounds, but the effect not being by any means satisfactory, but the effect not being by any means satisfactory, a machine was made on the principle of the synthetic curve machine, which would, by superposing curves on paper, reproduce eight partials by transferring the vibrations of the intermediate wheels to a vibrating tuning-fork, and the vibrations of eight wheels fixed on the same axis. The periphery of the wheels being cut into teeth of such a number as to correspond with the eight partials, in fact each wheel is simply harmonic curve, and the wheel represents one partial. The axis can be rotated at any speed. By depressing a key a vertical rod is brought into contact with the edge of each wheel, and a tuning-fork vibrates in accordance of those curves are transferred by this curve to an intermediate linking to a diaphragm of double, see Figs. 4 and 5, page 202, and by varying can be depressed variously by simultaneously by electricity, and the disc will vibrate to the resultant effect of all the curves. Two keys and chords can be sounded.

Here again, though the vowels were fairly reproduced, considerable difficulty arose in the superposition of numerous curves to be accurately drawn, and all the facts elicited by the examination of the curves, and all the facts above can be sounded by illustrations. Moreover, it forms the basis of a new musical instrument which has been constructed, and will be noticed.

With the hope of getting more perfect definition, another machine, with more ready means of varying the speed, and producing curves out in exact copy of the curves produced by the vibrations of tuning-forks. These curves are produced by vibrations of the receiving diaphragm of a phonograph, and readily traced on the surface of a cylinder of lampblack. The musically phonographic curves, Fig. 9, (see page 202), about 6 in. long, one end of which is attached to a fly-wheel, and the other end to a greased pulley G, round which a band or gut passes from a

driving wheel D, fitted with a crank handle E. On rotating the driving wheel, the long axle is caused to make about 60 revolutions per minute.

On the axle are placed, in such a manner that they can easily be removed and replaced by others, a number of brass wheels or discs a, a, a, &c., the peripheries of which have been cut by a machine especially constructed for that purpose into the different curves corresponding exactly to the curves obtained by the synthetic curve machine, and which is mounted on the same axle.

A diaphragm C with spring and frame H, similar to that in a phonograph, is so fixed that it can be shifted from one to another of the wheels, and the sound produced by the different curves can be readily compared with each other. A resilient vibrating reed is also fixed to the frame, by the curves can be readily compared with each other. By the help of curves related almost twice per second, and in the musical scale.

A number of combinations of curves have been cut on the phonograph cylinder, and the sounds produced by the vibrations of the brass discs, represented certain variations of the portials, or experimental determinations. These discs were then placed on the axle, and the sounds exactly resembling the vowel sounds of the human voice were easily recognised.

10. In this way it was found that from about *f* to *b* in

* Paper read before the Royal Society.

(2230) PHONOGRAPH AND PHONOPHONE.—The following item is clipped from the *Sunday Telegraph* of February 26th, about 3 years ago by Scott Tr.: "*The Times* of forty years months since," was the advice of Dr. Ellerby, lecturer before the Academy of Science at Union Hall. Now should there to the Indies proverb, and open first their eyes, then their ears, and last their mouths. If the mouth is duly inspected, its delicate functions during the day, it must be closed during the night. The lat- lows, wind-shoes, and mole-plugs that form the human voice must have their periods of rest, for sound is the result of motion. Wherever no produce sound we have silence. The old phe- nagaph, invented twenty years ago by Scott of London, and perfected by Koenig of Paris, was made on the principle of indentations of a needle on smoked paper. The new substitutes appearance of sound. One of them, being of wood like pipe, and is then charged with the melody of "My Grandfather's Clock," so that it clicked with such precision and deadened the de- sound with such distinctness of articulation, that the audience was highly amused." Will you please explain the mechanical operation, and oblige.—F. E. P., New York City. [?]

A NEW PHONOGRAPH.—Mr. Johnson, Mr. Edison's chief assistant at his Menlo Park laboratory, has been for some time engaged in improving the telephone and the phonograph. He has accomplished that no other one has ever yet been able to do—that is, the reproduction of the phonograph of words transmitted by telephone with such accuracy that they could be repeated by the speaking machine with sufficient distinctness to be understood. This was, of course, done by the employment of Edison's new electro-motor receiver, the only instrument as yet found that delicate enough and sufficient power for the purpose. Mr. Johnson has also nearly completed the invention of a new phonograph which he claims will be adapted to the practical use of business correspondence, and as proved by recording telephonic messages, greatly excels yesterday's experiment, will facilitate the use of the phonograph for business purposes.

A SIXPENNY PHONOGRAPH.

Whilst a great scientific discovery or invention is announced to the world, such, for example, as the telephone of Professor Graham Bell, the microphone of Professor Hughes, or the phonograph of Mr. Edison, it is pretty certain in a short time to be followed first by spurious and unauthorized imitations, which, if the invention be protected, are nothing more or less than direct infringements of the patent, and after that by highly interesting modifications of the ap- paratus either for the extension of the principle, developing further physical facts, or to analyze those already discovered; or else for the reduction of the instrument to its simplest possible form, so as to place in the hands of the teacher as well as in those of the million a scientific toy which can illus- trate and render familiar the principle which lies at the base of the more important and typical ap- pliances.

There are few who can have failed to see that both the telephone and the microphone have gone through both these stages; and the phonograph, after having been imitated by amateurs and copied, by unlicensed manufacturers, has led to the very beautiful analytical and synthetical apparatus of Mr. Stroh, and has quite recently reappeared as a curious and most interesting scientific toy, and one which we would hesitate to say could not be made applicable to some useful purposes.

The very simple apparatus which we illustrate below is a speaking phonograph that can be made and sold for sixpence or even less, and yet leave a profit to the manufacturer. It is the invention of M. Leontiegen, an inspector of telegraphs at Ahls, in the Department of Tarn, in the south of France, and has been brought to this country by M. Higelbaldet, whose name is well known in connexion with physical and electrical science.

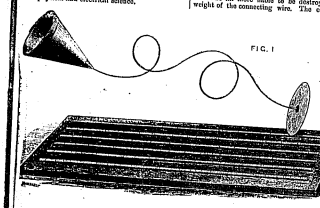

FIG. 1.

FIG. 2. FIG. 3.

The whole apparatus which is represented in Fig. 1 consists, first, of a button-cone of pasteboard about 1½ in. in diameter, whose apex is cemented in the centre of a circular metal pasteboard disc by means of a lead wire about 10 in. long; and, second, of a cardboard or tablet, on which is fixed one, or a larger number of short lengths of lead wire, each of which bears upon its upper surface a phonographic embossed record corresponding to a certain word or sentence, by which it was originally produced by a process to be described further on.

To those who are familiar with the construction of the phonograph in the form in which it was first shown in this country, and which was fully described in these columns some time in the year ago, it would appear necessary in order to reproduce the sounds recorded on the tablet, for the edge of the disc to be held in an annular frame so as to convert it into a diaphragm, and for its centre to be brought into vibra- tion by means of a point or style projecting from it and drawn over the undulatory surface of the record. But the method of using the apparatus is far simpler than that; all that is necessary is to hold the paper cone against the ear with one hand and with the other to take hold of the cardboard disc, drawing its edge along the record with a steady scraping motion, and the mechanical vibrations thus set up in the disc being communicated by the wire to the conical ear-piece which serves as a resonator and concentrator, produce in the organs of hearing the sensation of the articulate sound by which the mark- ings on the leaden record were originally produced. We should have thought that a sound thrown or a lighter wire would have formed a more efficient as well as a cheaper connexion for the purpose than the lead wire, but we are informed that M. Lambrigot has found the lead to answer the purpose better than anything else; it does not require to be kept stretched between the cone and the disc, and being of a very inelastic nature is does not spring about and produce disturbing sounds by clashing against itself or against neighbouring objects. Again, it would naturally be expected that the ear-piece would be more perfectly adapted to its purpose if it were in the form of that used in the ordinary thread telephone, that is to say if it consisted of a cylin- drical cardboard box closed at one end with a stretched paper diaphragm, to the centre of which the conical wire was attached, but simply as a fact, this would undoubtedly be a more complex form of construction than the cardboard cones, and would be for more liable to be destroyed by the weight of the connecting wire. The employment of cardboard as the material of which the principal parts of the apparatus are constructed is, in the case of the cone, for cheapness, and in that of the tablet partly for cheapness, but chiefly to protect the markings on the lead record from being destroyed, as they soon would be if a harder material than lead were employed.

The most interesting point connected with this very simple apparatus is the method by which the leaden records are produced, which is as follows: The top surface of a rectangular piece of glass, or other hard and rigid material, is thickly coated with shellac wax, which is then scraped into a convex form, as shown in the diagram Fig. 2, in which *a* represents the glass slab and *b* the convex casting of shellac. This bar is then fixed with a simple phonographic instrument, which, by means of a screw or other mechanical contrivance, traverses it at a suitably speed below a diaphragm. This diaphragm is rigidly held around its circum- ference by an annular framework (not shown in the diagram), and is in every respect exactly similar to the diaphragm of an ordinary phonograph. To the centre of this diaphragm is attached a thin flat piece, whose lower end is cut out to a concave curve to fit the convex surface of the shellac *b*. When all is properly adjusted, and the temperature is ar- ranged so as to give to the stearine surface the proper degree of hardness to insure the best results, the handle of the instrument is turned, and at the same time words are spoken against the diaphragm, which immediately set up in it vibrations, which are communicated to the plate or style. While this is moving up and down, following the vibrations of the diaphragm caused by the voice, the stearine coating of the bar *a b* is steadily drawn in the direction of the arrow below the vibrating bar, receiving from it a phonogram similar to that produced on the tin- foil of an ordinary phonograph.

The stearine bar is then coated with a fine surface of plumbago so as to give to it an electrically con- ducting surface, and it is then electro-plated with copper by the ordinary process. Out of the copper coating so formed the stearine is removed, and a rigid backing of lead or other metal having been run over the outside convex surface of the copper, a firm copper-lined matrix or mould is formed, the whole presenting the appearance shown in Fig. 3, and consisting of a rectangular block having in the centre of one of its sides a semi-cylindrical groove of copper which bears upon its surface certain raised striations corresponding to the depres- sions which were made by the diaphragm on the surface of the stearine. Into this groove is laid a piece of lead wire of about 3 or 4 millimetres in diameter, and the two being pressed into a press and squeezed together the surface of the lead wire receives a permanent impression which is an exact reproduction of the original impression made upon the stearine bar. One copper matrix is very large number of lead wire pressings may be made, and we are told that it has proved to be good for as many as 1,000 records, each containing the record of a short sentence, can be made and sold with a profit for one half-penny each.

It is an interesting fact that if a small stick of wood, such as the stem of a common match, be substituted for the disc shown in Fig. 1, and its end be drawn along the copper groove of one of the matrice moulds shown in Fig. 3, articulate speech is communicated equally well to the ear-piece, although the vi- bration of the point in the recesses of that of the disc, and this bears a very close analogy to the fact that in the ordinary Bell telephone a message is trans- mitted with equal distinctness whether the po- sition of the receiving instrument be reversed or not.

We have had an opportunity of testing this ele- little instrument, and the words come out of it in remarkable distinctness, though of course with a feeble power; and among the following words, of which we have heard it utter, some were decidedly clear: "Mon cher ami," "Louis Quatorze," "Victor Hugo," "La République," "Chemin de fer," "Banjore," "Lambrigot." "Microphone," "Phonograph," and "Electricité," and it is a curious fact that while the phonograph the words "Phonograph" and "Electricité" do you do?" come out with exceptional distinctness in this instrument the words "Banjore," "Lambrigot," the name of the inventor, "Lambrigot," are those of those we have heard.

It is only fair to Mr. Edison, the inventor of the phonograph itself, to point out that the process of producing a phonogram on a stearine surface, and afterwards reproducing it in copper by the aid of electrolysis, was suggested by Mr. Edison, but we do not understand that Mr. Lambrigot claims any novelty for that portion of the process, but more especially for having produced an instrument at the cost of a few pence, which demonstrates the action of the phonograph and illustrate some of the most beautiful phenomena con- nected with the science of acoustics. We congratulate M. Lambrigot on having produced a very beautiful methods by which he has brought it about, and we hope before long to see many use- ful little instruments very fruit their way in numbers to this country, for it is by the cheap and simplest apparatus that some the greatest discoveries of sciences are made to contribute to the intimate north in phenomena, but because popular instruments, accessible to the million, are the first tests for scientific investigation, starting them on a research which may lead to great findings, and out of the multitude of workers new inventions instigate, some discoveries of high certain to be made.

THE LONDON GAS COMPANY

is satisfactory to find that at least one of industry has escaped the depression most of the trades of this country. In every part of the country the present month investment shares of the shareholders of gas compa- of these we shall only call attention to the Gas-Light and Coke Company, the Chartered Gas Company, the Commercial, and Phœnix Gas Company, which stand next in impor- tance to the Gas-Light and Coke Company, that about two-thirds of the supply of Lon- don is given, perhaps a small ratio of the whole capital.

The accounts of the London Gas-Light Company showed an increase of rental notwithstanding the severe winter. After providing for the dividends on the preference shares there was a balance of profit for the half-year ending December, 1878, of 26,462*l.*, giving a dividend at the rate of 12 per cent. on the ordinary stock. As might be supposed, there was much little talk of the danger from explosion in the electric light. It appeared that the Board of this company had not been influenced by "electric scare," for out of a total of 500 miles of capital only about 14,000*l.* had changed hands during the year, and this chairman denied that there was any serious falling off in the consumption of gas, or any unless exceedingly favourable terms were offered. Mr. Robert Rawlinson, C.B., the well- known engineer of the Local Government Board, and a director of the company, stated that the electric light might be of service in exceptional cases, but was too costly. He exhibited the idea of

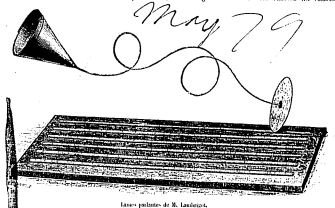
LES LAMES PARLANTES

DE M. LAMBIGOT.

Après avoir obtenu par le phonographe d'Edison une reproduction fidèle de toutes les vibrations délicates qui constituent le *son articulé* ou la parole, on s'est demandé s'il ne serait pas possible de multiplier indéfiniment le clichè obtenu comme l'imprimerie multiplie à l'infini le livre après une seule composition.

C'est ce problème qu'a résolu M. Lambigot par des procédés d'une simplicité remarquable dont nous allons faire connaître le principe.

Remplaçons la pointe du phonographe d'Edison par une petite lame d'acier en forme de cautcau et le cylindre tournant par un chariot sur lequel nous



Lames parlantes de M. Lambigot.

fixerons une laguette de verre portant une couche de stéarine sur une de ses faces.

En promenant un certain nombre de fois le chariot devant la plaque, la lame d'acier va racler la stéarine et en former une surface parfaitement unie.

Faisons passer une deuxième fois le chariot devant la plaque du phonographe avec une vitesse uniforme en parlant devant cette plaque, la lame d'acier, en suivant toutes les vibrations de la plaque, va venir strier la stéarine et former à sa surface une reproduction exacte des vibrations qui l'ont influencée. La stéarine, offrant une résistance moins grande que la feuille d'étain employée dans le phonographe, permet d'obtenir une reproduction plus fidèle des vibrations de la plaque.

La laguette de verre est enlevée du chariot,

le de plombagine du côté de la stéarine, et dans un bain galvanoplastique où elle se couvre d'une couche de cuivre sur la face où se trouve la stéarine. On obtient ainsi une matrice en cuivre reproduisant fidèlement toutes les vibrations tracées d'abord sur la stéarine.

En plaçant sur cette matrice en cuivre des petits fils de plomb de 1 millimètre 1/2 de diamètre, et en exerçant une pression convenable, on obtient sur le plomb une reproduction exacte du strioge de la stéarine; le cuivre étant plus dur que le plomb permet d'obtenir par pression un très grand nombre de lames avec un seul clichè en cuivre. En passant sur ces lames de plomb ainsi préparées un petit disque de carton, ce disque va suivre toutes les ondulations tracées sur les lames et vibrer de façon à reproduire très nettement les paroles inscrites par le phonographe enregistreur.

Pour rendre les sons plus perceptibles, M. Lambrigot attache un fil de plomb au centre du disque et fixe un cornet de carton à son autre extrémité, les vibrations se transmettent mol'écalrement par le fil de plomb et font vibrer le cornet qui concentre les vibrations sur l'oreille qu'on applique à son embouchure.

L'usure des lames étant insignifiante, on peut répéter plusieurs milliers de fois la phrase inscrite.

Ces lames permettent de répéter à plusieurs des expériences que l'on fait avec le phonographe; elles en jouissait le carton sur la lame à des vitesses différentes, on reproduit la phrase inscrite avec une voix de tonr ou une voix de basse à volonté. La vitesse moyenne est de 20 centimètres par seconde environ.

On peut concevoir un discours tout entier imprimé par le procédé Lambrigot sur un long fil de plomb qu'un mouvement d'horlogerie ferait dérouler régulièrement au-dessus du petit disque de papier

CHURCH ENTERTAINMENTS

That Instead of Sociables as usual, and dirt-dear paying bosses.

If Churches furnish elevating amusements they must be winning ones. Mind away from hurtful excitements. The Microphone, Phonograph and Telephone entertainment furnishes rare, refining pleasure. It will long be remembered by both young and old with pride as well as pleasure. The audiences has been great; in many cases netting handsome amounts to Churches and Societies. Everywhere where less novel and instructive entertainments have not paid expenses, intelligent people everywhere have rend so much about these wonderful inventions that they have been anxious for their development and hear an intelligent discourse on the principles of applying the whole subject [as well as some of the very wonderful future results]. The Telephone, with its instantaneous electricity of the evening, coupled with the great public interest in recent inventive development, makes the entertainment appropriate for any to-morrow of the year, and a paying one [necessarily].

Special arrangements can be made whereby the ladies can have at the close [on their own premises] a sociable with refreshments, if they may see fit. The Telephone can be postponed till first time and thereby a hungry audience held a half hour or more. Excellent results have been [in a few cases] obtained. Or, if desired, no-sociable arrangements can be made whereby a Concert ticket shall include, for instance, a dish of ice cream.

The new feature of

A Free Phonograph Matinee for Children,

in the afternoon, at close of day schools, assists greatly in drawing a large house in the evening. In matinees throughout the City of Philadelphia [in 78] delighted advocates, [with appetites aroused to [see the fullest extent in the evening,] and also furnishes a large number of active and effective those who they have heretofore ticket sellers from several different schools who work [in the evening] raising moneys for themselves.

The Matinee [when given *alone* results in a paying house for the evening, and has proved itself the best feature possible for selling to work up an evening financial interest.

An additional inducement to children to sell tickets before the Matinee, is, that all will sell the required number [as to as many be best in the locality,] can have *tickets their entrance ticket for evening*, a special one will be issued for the Matinee, [which will be good for that day only].

The invitation to the children to the free *Phonograph* Matinee [no other apparatus publicly used till evening] should be extended to the children through the public schools as early as possible, [several days before the concert day,] in order that the children may be talking the matter over at their homes, and thereby advertising the Concert.

THE PROGRAMME.

1st. Use of Speaking Telephones while the audience are assembling [testing speech, music, imitation, &c., over a long wire.]

2d. The Scientific Lecture, [about a half hour.]

3d. The Singing Telephone [heard throughout the largest room by all without effort.]

4th. The Phonograph [heard distinctly throughout the largest Churches or Opera Houses.]

5th. The Microphone.

6th. Examination and trial by the audience of Phonograph and apparatus, [when opportunity is given to all to ask questions.]

THE ENTERTAINMENT

has been everywhere pronounced first class.

The Lecture itself alone furnishes a good evening's entertainment.

Everywhere it has been accorded the verdict of "superior," "an entertainment of rare success," "a rich treat," "more worth more than the cost of the ticket," "the most instructive [and] entertaining lecture to which we have ever listened," "Leading intellectual men in the City of Chicago, with the history of marvellous success, [the result of hard work] are introduced as a stimulus to worry about the future or poor, as well as a matter of existent pride at his steps attended achievements.

Pour rendre les sons

bilator the jaws. The soldering fluid consists of equal parts of hydrochloric acid and water, in which is dissolved as much zinc as possible. A pile of books will be found useful for steadying the arm while manipulating the point. The diaphragm is fixed in its place by means of a brass flange (like a concert flange), 5in. in outside diameter, with a 2½in. opening. Four flat-head, withdraw the point by hand, turn the handle backwards until the cylinder is in its original position, and screw up the record nut until the second point proves lightly but steadily upon the bottom of the furrow. Then put on the paper remainder, and turn the handle at the same speed as before. If the adjustments are perfect, the result will be fair-sounding.

I will conclude with a few general remarks and hints.

It will be observed that this instrument has two diaphragms, whereas Edison's latest have only one, which does both the receiving and the speaking. I have made many experiments with the object of dispensing with one of the diaphragms, but I have never, under any circumstances, obtained as good results with one as with two. Mr. Preece told the Physical Society that the employment of only one was a retrograde step. Reason and experience appear to me to concur in his opinion.

I do not believe that iron and parchment-paper are the best possible materials for the diaphragms, though they are better than any others which I have hitherto tried. The great fault in the iron appears to lie in its tendency to resonate (ring). A certain resonance is certain tuned sounds. I have tried to overcome this by coating the diaphragm with India rubber, but with no great success. I think, however, that a ring of indiarubber between the diaphragm and the flange has an undoubted effect in diminishing the misonance. Paper is also subject to independent vibrations of a similar nature. These may be diminished by coating a piece of soft indiarubber to a delicately spun it at a point about 1in. below the *lower strip of lamé*. I have also found it an advantage to wrap indiarubber round the top of the spring before screwing it on.

I believe that the mouthpiece of a telephone would give better results than that of a speaking tube. A long resonating mouthpiece like that which Edison first used is worse than useless.

The point on the steel spring should be made to turn very slightly upwards instead of being perpendicular. In the latter case it is liable to produce a squeak something like that of a slate-pencil when drawn upside down across a slate.

If the points are too sharp, they will cut and scrape the tinfoil ; if too blunt, the articulation will be muffled. After the points have increased the cylinder 200 or 300 times, they will require sharpening. This can be done with a small oil-stone, without removing them.

In conclusion, I may mention, for the encouragement of those who wish to make a phonograph, that the performance of the instrument here described is at least equal to that of any which has hitherto been exhibited in London.

THE ORGAN: A COMPREHENSIVE TREATISE ON ITS MANUFACTURE, PROCURAL, AND LODGMENT.*

By JOHN WARNER WALKER, M.A.,
Associate of the College of Organists, London.

PART I.—GENERAL TREATMENT IN MANUFACTURE.

I T will be seen that, in the features given, there is no provision for pneumatic or for Pedale to keep it distinct from the Manual four or five disturbing 16 intonation of the latter. The simple reason is, that such provision is found to be an indifferent infrastructure. The Pedal will thereafter Manual less in the proportion of 16 to 8 than any part of the Manual will disturb Pedale. *See* Sec. DETERMINATION OF NUMBERS or PARTS (22.)

8. *Tenor Organs.* (See Swell Organ, Stiehls.) It is a very great mistake to have the tenor on too heavy a wind ; the dignified stop

Sc. Am. Aug 9 1879

(55) A. D. writes: Referring to the phonograph described in Supplement, August 9th, 1879, No. 175, will you give more definite instructions regarding the construction of the little wooden spring, size, form, and kind of wood? A. The accompanying

diagram gives the exact size and proportion. A being the portion attached to the wooden pivot, B the portion that rests upon the diaphragm, and C the needle. The width should be about 3-16 inch and the coil, B, should rest with some pressure upon the small soft rubber block placed against the diaphragm. Any wood that springs well will answer; fichy is perhaps as good as anything.

LE PHONOGRAPHE

La Science Pour Tous July 19 1878

A l'époque où parut le phonographe d'Edison, nos lecteurs se souviennent que nous leur en avons donné une description détaillée. On se souvient aussi que cet appareil consiste en un cylindre de cuivre fileté à la surface duquel on applique une feuille de papier d'étain et de plomb. Sur cette feuille appuie la pointe d'un stylet supporté par un ressort d'acier, lequel est mis en communication avec une plaque vibrante fixée au fond d'un entonnoir en métal de la forme d'une embouchure de trompette. Le cylindre porteur de la feuille d'étain est mené sur un axe à vis qui peut avancer ou reculer dans un écrou, suivant que l'on tourne une manivelle dans un sens ou dans un autre.

Quand on parle dans l'embouchure, la plaque du fond entre en vibration et chacune de ces vibrations influence le stylet au point de lui faire exécuter un mouvement plus ou moins rapide de va-et-vient. Chaque fois que le stylet est lancé en avant, il laisse sur la feuille d'étain une trace, une légère dépression. Si le cylindre restait immobile, le stylet frapperait toujours à la même place, accentuerait la dépression, et aucun résultat ne serait produit. Mais si, au moyen de la manivelle, on imprime au cylindre un mouvement lent de rotation, les dépressions produites par le stylet se trouvent, formant suivant les sons et, par suite, les mots des lignes, des séries de dépressions différentes les unes des autres. La phrase étant terminée, le stylet est soulevé, le cylindre ramené à sa position première, puis le stylet presse de nouveau par sa pointe sur la plaque. Si, alors on imprime de nouveau au cylindre un mouvement de rotation égal comme vitesse au mouvement précédent la pointe du stylet repasse par les traces qu'elle a laissées, elle est donc alternativement soulevée et rendue libre; son mouvement se communique à la plaque vibrante qui produit des vibrations, lesquelles se trouvent répéter les vibrations, par suite les sons et les mots qui tout à l'heure l'actionnaient.

Cette répétition des vibrations produit donc, en fin de compte, la répétition des phrases, et rien n'est plus curieux, en effet, que d'entendre la voix de crécelle vous répéter les mots que vous avez prononcés dans le cylindre porte-voix.

Jusqu'à ces derniers temps, le phonographe était un appareil trop coûteux pour la plupart des physiciens amateurs, mais aujourd'hui un ingénieur, M. Pech de Cutel, a réduit à 25 francs le prix du phonographe d'Edison, et cela sans en supprimer aucun organe, sans négliger en rien les soins de fabrication. Ceux de nos lecteurs qui nous ont témoigné le désir de posséder le phonographe le trouveront dans nos bureaux au prix indiqué plus haut.

The Deaf Hear.

Mr. Editor: I have just read Mr. Jos. R. Freeman's communication on "The Teeth and Organs of Hearing", published in this week's issue of THE ADVANCE. Mr. Freeman copies from a lecture by Dr. Wooder, of Boston, in which "the teeth", says the doctor, "have the faculty, in common with bodies of bone, of receiving and transmitting the vibrations of sound. The deaf can hear by means of their teeth being connected by a rod of glass or hollow wood to a musical instrument, the piano, for instance."

The deaf mute adam
aug 30 1879

The above is a fact, as I have long been accustomed to *listening* to musical instruments, especially the piano and organ, by a stick or wire (wire is better than a stick), and more often by putting my teeth on the edge or corner of the instrument. By these means I have been able to hear, not many sounds, but the real music in all its force and beauty, even down to the softest or softest sound, even as well as those who do not deaf at all! And as I am by nature fond of music, I am thrilled to a rapturous delight, far beyond what is commonly enjoyed, perhaps because I hear it only once in a long while. The last time I listened thus to an organ, I was sadly affected, almost to tears, because my deaf and dumb wife and I were not able to enjoy such delightful things in common with other folks. I arose and left in haste, my friend who played, for me stopping me, saying, "what's your hurry?" I told her that the music caused me to feel keenly the loss of my hearing. She seemed affected at the idea. I so keenly felt my misfortune, and seemed to realize then and there, as she never had before, notwithstanding her long acquaintance with us and other mutes, of some eighteen years, how sad it was to be deaf.

The blind and the cripples are easily detected by external means, manners and appearances, and the public are constantly reminded of their misfortune, and by this repeated reminding give much aid, also thought to their condition, such, day. But not so with the deaf and dumb, whose misfortune is entirely hid from sight; we may pass one thus afflicted a thousand times, and not know that he or she was deaf and dumb. And even when people discover them by a chance sign, or their not replying to questions and remarks when spoken to, they appear so cheerful, and show no unsightly contortions of the body or face, that people's sympathies are not so fully aroused as they are by the blind and crippled, and hence give little heed to them, little aware that many of those who are deaf and dumb have no hard a road to travel, as to a living, as other unfortunate people, and ten times less enjoyment of life in the way of friendly voices and sweet sounds, &c. Please excuse this little digression and dilating in behalf of the deaf and dumb.

Mr. F. quotes from *The New-York Post* to show that this idea of hearing by or through the teeth was known as far back as 1875. It was original with me, and an experimental discovery, so far back that I have forgotten the exact date, but think it was when I was between fifteen and twenty years old—some thirty-five years ago—between 1836 and 1850. Ever since then I have known more or less what instrumental music is, and have enjoyed it occasionally, or whenever I had a chance to listen (?) to such through my teeth, and it was by this means that I learned what very soft, low sounds are. Becoming deaf at three years of age, I have no recollection of such sounds, &c., by the ordinary hearing. Here let me digress again to say that if Mr. E. P. Needham, of 143-7 east 23rd street, New York City, will improve his mechanical musical cabinet (a reed instrument, as arranged that deaf people can play it as well as any one else), so as to attach a wire or hollow glass rod to it, and hold the same between

"the teeth while sitting in any easy position, playing the cabinet, it might induce deaf people to become his customers, as half is the best cure I have yet seen that deaf people can play to perfection, but not to hear or enjoy it for want of this suggested improvement.

The great electrician and inventor, Prof. Thos. A. Edison, of Menlo Park, New Jersey, has been and still is, as I understand, working to invent an instrument for deaf people, he being deaf (?) himself. His aim is to find how to collect a great volume of sound, or concentrate it so that deaf people can hear it, equal to, or almost as well as, those not deaf. My own experiment in the matter of a greater volume of sound is a failure. It is not always the loudness that is wanted, as it too often confuses, but the ability to distinguish between the different sounds, which I have only been able to do by the *teeth*. But as the wire does not affect the listening (?) wire as a musical organ, the idea strikes me that if Prof. Edison will connect a wire or something with his "sound-collector" that can be held between the teeth, he will then have what he has long sought after, the connecting or distinguishing link—the link between the living voice and the deaf ear. Yours, &c.,

P. A. EMERY.

Chicago, Ill., Aug. 10, 1879.

P. S.—There seems to be quite an increase of deafness among grown people, and an increase of some 23 per cent. of deaf and dumb among children, of late years. Years ago it was one in every 2,000, and then increased to one in every 1,500, but now it is more like one in every 1,200, contradicting the idea that deaf-mutes would decrease as people advanced in intelligence and the multiplied art. Out of the 25,000 or 30,000 deaf-mutes in the United States, I suppose a good 'sixth telephone' would be of use to ten per cent. of them—3,000 to and 90 per cent. of the semi-mutes.

Scientific Sept 25 1880

TELEPHONY AND TARGETS.

TO THE EDITOR OF THE ELECTRICIAN. 19

SIR: It has occurred to me that the telephone might be used to obviate the possibility of a "Wimbledon scandal," and to avoid those accidents which happen, although rarely, to marksmen.

The third or "flash," as it is called, of the bullet against the target is of a different pitch according to the distance it strikes from the centre. A telephone in circuit would enable a person to distinguish this distance with a little practice.* A committee could then record the scores, or a phonograph could record the sound and reproduce it at any time. W. H. A.

Miscellaneous.

MODERN INVENTIONS. 19

By PAUL CLERGE.

A clatter of bows, a flash of light,
A telegram speeds through the silent night.
Nobody sees the electric spring,
Or hears the rush of the busy wing;
But lives are slackened with grief and pain
When the message is caught from the wire again.

Nature a moment's delay, the electric fire
Flashes again o'er the quivering wire;
Gathers the hours, speeds the lightning spark,
Another message leaps out of the dark,
And lives are heightened, and hearts are glad,
That a moment before were dark and sad.

'Tis a marvellous age when the words of man
In a moment of time the world can span,
Just, accustomed to wonders, the present age
Demands for its rightful heritage
The works which the brain of the past has wrought
By ceaseless labor and tireless thought,
And the voice of the present, unsatisfied, cries
For something that's new 'neath the sun and skies.
Obeying its summons, the telephone
Comes forth with a soulful "Hello!" (groan;)
While the speech of to-day, both in wind and shell,
For to-morrow is stored in the phonograph.

SCIENTIFIC PROGRESS.

19

Practical Value of Science.

Our obligations to the branch of physics are almost unlimited, but we will mention only two or three applications of a single agent in this wide field. It would seem to roll back the world into the dark ages to take from it now the benefits of electricity in the multiplied and yet rapidly multiplying applications.

It seems incredible, from our present standpoint, that the first talk we, in our congress-hall talk, by electric telegraph was almost ridiculed into oblivion, from which it could never rise, when a bill was presented, appropriating money for the wires, under the direction of the Postmaster-General, in a series of experiments to test the merits of Morse's electromagnetic telegraph; six members moved appropriations for the purpose, and by the encouragement of mesmerism, Professor Daguerre proposed to institute Millerism in the shape of the appropriation others to appropriate part of the sum to a telegraph to the moon! And when the bill came to a final vote, this was so close that a change of three votes would therefore have left us till this day without the use of the telegraph. After the invention of the electric motor, and transmitting messages between Baltimore and Washington, Mr. Morse offered it to Congress, to be managed by the Postoffice Department, for the sum of $100,000. This was declined, on the statement of the Postmaster-General, who reported that, while the investigation "an agent vastly superior to any other ever devised by the genius of man, has been fully established in the year 1838, he was unwilling with a permanent magnet; around the two poles he had fastened wire coils, and struck up the tune on the magnet by drawing a violin bow across the ends of the coils. Instantly through two miles of wire a similar tune played on a magnet at the other end. The publisher then in Silliman's Journal in 1837. The scientific journal of London, Edinburgh, and Dublin, in the same year, declared that "we were never more convinced of the truth of any scientific deduction than we are of the practicability of electro-magnetic telegraphing. And if he were to make three very small discoveries, and do this frequently, he would be the most popular man in the world." Now,

MODERN WONDERS.

The phonograph catches the tones of the voice, stores them up and restores them at will to the hearer. The voice that comes from the grave. The voice that comes from the grave. The voice that comes from the grave

66

Boston Times Mon.
Oct. 23rd 87.

Edison's latest triumphs with his phonograph are as marvelous as anything which has ever been received from him. So delicate and accurate is the invention that it will reproduce, he says, all the different tones of an orchestra so distinctly that the several instruments can not only be distinguished, but a trained ear can recognize the over tones in the violins. The machine has simply to be set in motion by an electric motor and talked into. Then it will reproduce all that was said to it. The fall on which the impression is received may be sent by mail any distance, or kept for any time, or used repeatedly, all without injuring it. Such an invention will be of inconceivable practical good to business men and to public speakers.

Edison is giving to mankind far more than will ever be returned to him under any patent he may ever take out. His service, though it may result in a great fortune to himself, is to mankind contrast to the lack of service rendered by men who make their fortunes by their wits, men who take advantage of corners and rattle on stocks to squeeze somebody else and get their property. They add nothing to the world's stock of goods, but Edison gives far more than a quid pro quo. His gives more than will ever be returned to him, for his good work will go into every civilized community and will go down the ages for all time.

THE NEW PHONOGRAPH.

When Mr. Edison's phonograph first made its appearance wonderful claims were predicted for it. It was, indeed, a wonderful instrument, but it has not been very useful. Now, however, Mr. Edison has substituted a new and improved phonograph which he says will really do many of the things which it was expected the old one would be good for, for speech is one of its greatest uses.

Mr. Edison sets forth some of the uses of his new phonograph in an impressive way He thinks that every business man will hereafter have one. The merchant or clerk who wishes to send a letter has only to set the machine in motion and to talk in his natural voice and at the usual rate of speed into the receiver. When he has finished the sheet, or "phonogram," as Mr. Edison calls it, is ready for posting into a little box made on purpose for the mails. He is making the sheets in three sizes—one for letters of from 800 to 1,000 words, another size for 2,000 words, and other size for 4,000 words. The receiver of a phonogram will put it into his apparatus and the message will be given out more clearly, more distinctly than the best telephone messages ever sent." The tones of the voice in the two phonographs which Mr. Edison has finished are so perfectly rendered that one can distinguish between twenty different persons, each one of whom has said a few words. One advantage is that the letter may be repeated a thousand times if necessary. The phonogram does not wear out by use; moreover, it may be filed away for a hundred years and be ready the instant it is needed. If a man dictates his will to the phonograph there will be no disputing the authenticity of the document with those who know the tones of his voice in life.

For musicians Mr. Edison says the new phonograph is going to do wonders. In the early phonograph of ten years ago, which was a very imperfect and crude affair compared to that of to-day, it was always noticed that musical sounds came out peculiarly well; the mainline would whistle or sing far better than it would talk. This peculiarity of the phonograph remains. Mr. Edison has taken down the music of an orchestra, and the result is marvellous; each instrument can be perfectly distinguished, the strings are perfectly distinct, the violins from the cellos, the wind instruments and the wood are perfectly heard, and even in the notes of a violin the over tones can be heard in a delicate way.

Mr. Edison has experimented with a device for enabling printers to set type directly from the dictation of the phonograph, and thinks that it will work to a charm. It is so arranged that the printer by touching a lever with his foot allows five or ten words of the phonogram to be sounded; if he is not satisfied with the first hearing he can make it repeat the same words over and over again until he has them in type. For busy men who dictate a great deal for the press Mr. Edison is sure that the phonograph will be a necessity after a very little experience.

It remains to be seen whether these expectations are or are not realized. But there is no doubt that Mr. Edison is a very wonderful man.

EDISON'S GREATEST WONDER.

HIS PERFECTED PHONOGRAPH THE LATEST MARVEL.

What the New Invention will Do—Vast Possibilities Possible Inventions to Do Away with Letter Writing and Printing—A Feast of Literature and Music for Four People—What Other Scientists Say About It.

New York, October 21.—Special: In the history of prosperity Thomas A. Edison is still the unprecedented, interesting man that he was many years ago, accessible to every one who has any legitimate business with him, intensely interested in every department of science and invention, and the possessor of more than a merry share of intelligence whether an expert in the field of invention or merely an interested observer. There is no greater contrast between Edison's personal position now and in the early days of struggle which ended with the business success of the phonograph in 1878 than the same. Edison never ceased to have interest the electric light in the broad sense of the term; he did claim to have as perfected the lamp that it passed from the laboratory to the commercial state of existence, but of course it became a world factor. The same is true of the motors in the two phonographs which Mr. Edison has finished are so perfectly rendered that one can distinguish between twenty different persons, each one of whom has said a few words. One advantage is that the letter may be repeated a thousand times if necessary. The phonogram does not wear out by use; moreover, it may be filed away for a hundred years and be ready the instant it is needed. It remains to be seen whether these expectations are or are not realized. But there is no doubt that Mr. Edison is a very wonderful man.

67

While "human nature feels 'frightening' out" Dudley he still takes an active part in each of three vaudevillians, but he looks upon the whole scheme as practically finished, and his attentions are to simplify or discard.

With the extension of the Edison electric light, the question of money for the inventor himself has become a secondary one. Edison's work is a philanthropy. Probably would still spend ten hours a day in his laboratory if he had his choice. He has a large staff of skilled mechanics and other workmen in his employ, and they are with his own hands, and gaining further pleasure out of this detail work. But Edison's personal money has passed out of value to him in making possible all sorts of costly experiments in every direction of science, and pursues the study of science for experts, perhaps for months, which are of really tantalizing and interesting.

In the laboratory which Edison is now building within sight of his superb country home at Orange, New Jersey, he will realize the dream of his life. He has long been engaged in developing the ore-milling plan, such ore more than one-half of which is low grade, and putting through millions of tons of it in the most substantial manner. Edison's interest in this direction for the commercial work which the scientific mind can do for the world. In the most perfect workshop of this kind in the world. It will be limited by what the highest by electricity and modern machinery can accomplish in every possible device for the economical handling of ore, and the most effective and rapid results. In the department of materials Edison has already begun a study from which he will have experiments, every metal, every wood, that can be found in the world for experiments. He has already the mineral and vegetable kingdoms ransacked, and from the latter he thinks he has been laid under contribution, for he has tested nearly half a ton of every kind of remaining. Sitting in his large factory office, surrounded by patent attorneys, engineers, and experts in the fourth story of the great building, and looking out upon the river, one can spell through half a dozen machine shops as many more workshops, smoke permeating the air, no one visitors may not get within the inventor. Edison said in his quiet way: "I have no time for visitors. I do not see rather what will happen. I get a world-wide, every time, in short, everything that the scientific men can imagine is of possible use. As one instance of the value of the phonograph, I may say that it has been stripped from the two days in his work upon the quadruplex system of sending electricity directly from spark to spark need of a sufficient quantity of nickel; he knew that Edison was in Europe, and he sent a man during his visit to Europe to have conversation with Edison, and for him to be found in this country.

Of all wonders that Edison has devised this coming phonograph, which he claims will reproduce the human voice in such a manner that it will be impossible to distinguish the tones of the original sounds was, in the Edison phonographs which were shown in this city years ago in different parts of the world, singing, whistling, and a great many instruments, but to really distinguish the individualities of the musicians was impossible. The new phonograph, however, for the reproduction of speech, it was a phenomenal success. Under a great, intelligible result at all it was necessary to speak for some little time, close, and even then the words were often but a mere caricature of the original. The new phonograph was undertaken and carried through and was then placed upon laboratory table as a curiosity.

About 1877 the electric light began to take up all Edison's attention, and from that time until within the last year he has had but the slightest connection with the phonograph. He says himself that he became a perfect "dumb Dutchman" in the matter of knowledge of the phonograph when, not with the diligence and energy which he has since displayed, he took up the work. He has since made the phonograph more of a wonder than it was in its conception or the splendid possibilities of the instrument, and

EDISON'S NEW PHONOGRAPH.

One would regard Edison's latest idea as an absurdity, if it be that he must have specimens of every kind of material that the world affords—animal, vegetable and mineral—stored away in a storehouse so that he can lay his hand on them in a moment of need. The list of minerals alone will be quite large, but he would the variety can be very great. Edison is said to be much annoyed by having to send to Japan to get bamboo for cartons, and to England for nickel, and the like; and therefore he will have all these things handy if possible.

Lately Mr. Edison has been working in his new laboratories at Llewellyn park, New Jersey, where he has three large buildings, each 100x50 feet and four stories high, in which to conduct his experiments and to manufacture his electrical and other apparatus. Edison's fame rests largely upon his telephonic, phonograph and electric light system. But these are a small part of his numerous and useful inventions.

His energies are now bent upon the practical improvement of the wonderful phonograph, which at present is only a scientific toy. This, with his electric lighting apparatus, and the new cotton picker and the steam car motor, keeps Mr. Edison so busy that his young wife begins to regard his inventive genius as a positive nuisance. Nevertheless, he is a most devoted slave of the lamp—electric lamp—and turns out about 1,000 of them per day. He says that his new commercial phonograph is so wonderful, as now perfected, that no one would believe him if he told what it would do. The former phonograph was only the germ of this. When the electric light assumed commercial importance, Edison "threw everything overboard for that," and placed its manufacture on a good and enduring basis. Which shows that Mr. Edison is not only lucky and ingenious, but shrewd as well. The new phonograph is certainly a marvel. It runs by clockwork, which is set in motion by power from a small battery, so that the motion is noiseless and steady. It records its words upon a phonogram, or card, which can be sent by mail, and is not easily damaged. This card can be used over again any number of times, as occasion requires the message or letter to be erased. All that is necessary is to run the phonogram back thro' the same or another phonograph, and the message is "talked back" as distinctly as it was spoken into the receiver. Not only is speech easily and perfectly recorded, but as was noticed to be the case in the former experiment, music is still more distinctly recorded, so that by the multiplication of the phonograms, which is easily and simply done by a copying process, the music of the finest orchestras and sweetest singers can be issued up and sent to any part of the country by mail or express, to delight the ear and soothe the wearied mind.

By a rachet attachment the machine can be made to talk a few words at a time, and the editor seated in his luxurious chair can breathe wisdom into his phonograph, while the typo with his foot on a lever can have a similar instrument on his case, and by running the phonograms or sound sheets thro' the instrument set type from it as fast as the machine will talk.

Of course there will be occasional lapses of speech in the "copy," which the intelligent compositor must learn to recognize and avoid. The annual visit of the spring poet, who interrupts a half finished editorial on the tariff question, will of necessity bully into the copy, and Mr. Edison must invent some kind of a safety shut-off which can be applied to the receiver at proper times.

For business men, the new phonograph will be invaluable. But it will make sad havoc with expert stenographers and penny typewriter girls. The kings of business and mines, instead of dictating to shorthand clerks, will merely sit still and talk all day. However, in this age of luxury, they will in many cases speak only a few sentence words, leaving the phonogram to be filled in or out by expert talkers. Here's where the women will again come to the front, and as it is universally acknowledged that they have no superiors in the art, they will, of course, be generally employed. In fact it will soon be a much larger field of labor to them, for whereas only a few women are equal to the straits of an editor's work at the typewriter, any woman could talk all day into a phonograph and still feel fresh and vigorous at the end of the session.

Verily if there are to be any more statues set up in the house of representatives, let there be two kept cool, one for Edward Burgess and the other for Thomas A. Edison.

Newburgh Herald, N.Y.
Oct 25th 87

Edison's perfected phonograph, if it should prove to be what he claims, would be of great utility, and very easily might prove a great success. That which was published from time to time years ago, was in-distinct in enunciation, so that it required a quick ear to catch the words and the tone was squeaking. He says of the perfected instrument that it is plainer to be understood than the telephone as the best, and that the tones of individual voices can be distinguished. The matter is regular and moderate, and the talk can be repeated a thousand times without wearing out, while the record can be used as cheaply as ordinary letters. It would be exceedingly awkward in some instances to have one's exact words and tones of voice accurately recorded, so that there could be no doubt nor denial. If a public man wanted to modify or explain away an unfortunate expression, it could not be done if the report of the speech were taken by the phonograph, inexorable as fate, and accurate as the stars in their course.

New York Tribune, Oct
Oct 25, 87.

SAVING AND MAKING LABOR.

Mr. Mr. Edison's claims in regard to his newly perfected phonograph are not exaggerated ones but assuredly have a most important addition to the world's ever expanding list of labor-saving machines. It will outrequal the telephone nor the dynamo machine nor the cotton gin nor those wonderful, mechanisms which at one period revolutionized spinning and weaving and, in England, led to the machine breaking riots. But a quick substitute for letter writing, a machine which may take the place of both the type writer and the telegram pen, which dispenses with amanuenses and substitutes spoken speech for slow penmanship is surely what be classed as one of the truly great inventions of the century. It belongs to the division of inventions which add to the capacity of the world's productive forces, especial industries, to which they are applied and which are apt to be viewed with alarm, naturally by the people whose very livelihood they threaten. Invariably, however, by such discoveries in general who know not what many connection next to superiors the work of their hands.

It is a great and wonderfully intricate question this of the source of labor-saving machinery, on the condition of the laborer. Economists differ widely both as to the results which have followed in the past and those that are to follow. A good many attribute our present labor troubles in the lower state to which powerful machines have brought our industrial classes while quite as many unconditionally contend that labor saving machinery has positively lessened the condition of the workers. But a few facts the experience of everybody will confirm. When that every piece of labor saving machinery creates a certain amount of new labor and work in making the machine itself which in various parts has to be handling its speedy production. A second and very vital point is that every cheapening of the cost of the article enlarges its demand and thus enforces a greatly increased supply. Illustrations of both these points will crowd upon memory. The invention of the locomotive, for instance killed off many stage lines but it upbuilt a vast industry in creating locomotives railroads and the operation of both. The discoveries in the work of ... substituted in the ... work of ... for girl or of a young boy for many adult men cheapened the product but so enlarged the demand that cotton and woolen and silk mills all over the world employ ... to ... millions of operatives. The sewing ... ches doubtless threw many seamstresses out of work but it opened labor for thousands in the factories which stitch, cotton, ready-made clothing and scores of other articles are made from textile fabrics. It is now saying to one direction but about the work on a ... Will this phonograph do so, or will ... very finally overtake all these factors? ... the time ... [illegible]

A Wonderful Device.

The readers of the TIMES have already been informed of the perfection of an instrument invented by Mr. Edison which will, as small exploit, record the sound of the human voice, or any other sound, for that matter, and reproduce it in miniature with a perfection which leaves nothing to be desired. The principal of the new phonograph is a vibrating diaphragm armed with a short point which indents a moving sheet of metal according to the vibrations caused in the diaphragm by the wave sounds which strike upon it.

In an interview with the inventor, the *New York Evening Post* learned many things about this remarkable device and the possibilities and probable extent of its usefulness and application. Among them are the following set forth in an editorial summary by that paper:

"For commercial purposes his phonograph, he says, will allow the hurried business man to dictate his correspondence without the aid of stenographer or typewriter; he will simply talk quietly into the machine, and when the letter is finished he will have a sheet which can be sent by mail, and which, when placed in a similar apparatus, will reproduce the original sounds, so Mr. Edison expresses it, "for more distinctly and with far more of the characteristic accent of the voice than the telephone ever does."

If it turns out that the Edison phonograph does half of what is promised, it requires no great stretch of imagination to foresee most wonderful things for it. As the reproducing apparatus can be made to work slow or fast at will, the operator at his case may listen to the phonograph and set up his type accordingly. The invalid or the busy person may at a trifling cost have all the great lecturers of the world without leaving his arm-chair, by touching a spring which sets the phonograph in motion and providing it with the proper roll of the foil. The business of the professional reader will be gone. The cost of duplicating the sheets of foil, or other material upon which sounds have been imprinted, is said to be so trifling that whole books will cost, as "phonograms," less than they do now in print, and will occupy far less space. In the old phonograph the frequent passage of the foil under the reproducing part of the apparatus caused a gradual obliteration of the indentations and a consequent loss of clearness in the enunciation of the instrument. This defect is said to be overcome, and the same message or letter or book may be repeated thousands of times without any deterioration. If books can be repeated upon the phonograph, why not newspapers? The field of speculation is endless.

With regard to music there seems to be no doubt that the new phonograph will achieve much that is promised for it, for in the very earliest of Mr. Edison's devices of this kind, the clearness of musical sounds, or singing, compared with spoken words as reproduced by the phonograph, was very noticeable. Songs could be understood, word by word, when spoken messages were unintelligible. From the experiments made with the two instruments already finished, it has been found that the phonograph is incomparably superior to the telephone in its interpretation of the music of any kind—singing, the piano-forte, the violin, or the complex sounds of a whole orchestra. The different instruments in a small orchestra can be perfectly distinguished, and the difference of tone is so minutely conferred that one can tell which of two pianos of different makes was used for playing a piece of music reproduced in the phonograph. The cheapness with which reproductions of the phonograph foil may be made will, it is said, make a whole opera, thus given in miniature, orchestra and voices, cost less than the most worthless piece of sheet music does now. As the phonograph will reproduce whatever it hears, the playing of a Rubenstein or a Joachim or the singing of a Patti may possibly be heard with a pleasure for centuries to come. In fact, as we have already said, the more one thinks of the possibilities of a perfected phonograph, such as Mr. Edison now soberly tells us that he has devised, the more bewildering the outlook becomes."

Ut. Morning Leader, Iowa
Oct 25th 1887

A GREAT INVENTION.

News of tremendous import comes from the workshop of Thomas A. Edison. It has been hinted at in THE LEADER for some months, but now it comes from Edison himself, and it is more wonderful than we had imagined. And this is the substance of it.

The phonograph is ten years old. At the Paris exposition it was awarded a premium as the most wonderful invention of the century. But before it was perfected to the point of practical, every-day use, the inconcerent light struck a winning gait, and absorbed the inventor's time and attention, so that the phonograph was crowded out of his mind.

He has lately taken it up again and has transformed it into one of the most remarkable inventions of the day, as well as the most wonderful. He has two perfect machines made, just as they are to go on the market, and hopes to have 500 ready for sale in January.

The principle of the phonograph is probably understood by all our readers. Sound is caused by vibrations of the air. Loud sounds are caused by large vibrations, high notes by rapid ones. All differences of sound are therefore caused by the differences in the size and rapidity of the vibrations. Fasten a pointed cone of horn or metal on an elastic diaphragm, lay a sheet of wax parallel with the diaphragm and just far enough away so the point will barely touch it when at rest, then talk and move the wax sheet and the point will make impressions in the wax, which will be deep or shallow, according to the loudness of your talk, and close together or scattered apart according to the pitch of voice in which you speak.

If you stop talking, and run the wax through the machine exactly as it was first traversed before, it will do the talking itself this time. You have a rude phonograph. Edison has made one that isn't rude. The foil he uses is probably not wax, for it won't wear out until it has repeated your words a thousand times. And besides, it can be copied any number of times, and very cheaply.

This is the interesting part of the story. This foil can be sent around the world, or kept a hundred years, or multiplied by a hundred thousand, and when put into the receiver the phonograph it will reproduce not only the words but the tones of the original speaker. Some of the foils will hold one to 1,000 words, and others as high as 4,000 or more. The message conveyed by one of them is called a phonogram. It can be heard much more distinctly than any telephone message.

The uses of these phonograms are so many and important that the future they promise is fairly unthinkable. They may be sent through the mails like ordinary letters. They may be copied, and the

New York Sun
Oct 28 87.

copies jointly bound together into books. Reading will be made as easy and pleasant as listening to a lecture, and the eyes will be saved. They may be used as printer's copy to set type from, the printer slapping at every few words, and if he don't quite catch them sensing, he can make the sensitive repeat until he does.

In fact, the phonograph, if it does what Edison claims that the two already manufactured will do, is bound to take the place of the type-writer to a great extent. The business, instead of dictating to a girl, will talk to his phonograph. Not one of his words will be either omitted or misspelled. He can retain a copy. The success of correspondence an ordinary man will be able to attend to is simply enormous.

The probable uses of the new invention are also important. It always did do better work on words than on conversation. The new song you buy, which will cost you less than at present, will come to you neatly in cold black and white, for you to lecture, post into vocal music, but in the voice of some good singer, full of expression. So you may sing it correctly if you like, and if you don't sing you may enjoy the song anyhow. Your phonograph will be all the musical instrument you will really need, in order to have a world of musical enjoyment. For not only will it repeat the concerts of the single instrument, bringing out the soft and soul of that instrument, but it will give you a whole chorus of voices or instruments, and even an opera. At last no shall all have a chance at Wagner.

All this Mr. Edison promises us, not in the uncertain future, but just as soon as he can get the machines turned out and put on the market, and this shall begin to be realized yet this winter. So we shall not be obliged to walk long.

Oct 28 87.

A WONDERFUL WORKSHOP.

The Resources of Edison's Laboratory.

What the New Phonograph Is Expected to Do—Work Upon the Great Electric Generator—A New Cotton-Picker and a Street-Car Motor.

Eight miles of Delaware, Lackawanna, Orange, New Jersey, Thomas A. Edison, the inventor, is now hard-fisted wizard promises to be the most perfect physical and chemical experimental laboratory in the world. His laboratory at Menlo Park is to grow too restricted for the needs of the inventor, a body of expert workmen whom he have continuously employed in carrying out the suggestions which he makes to them. For years he has wished to build such a laboratory as he is now finishing, and to embrace that this use of money is that which has given him the most pleasure of recent years. The new laboratory building has an eighth of the pleasant country house which Mr. Fedder, the former master at Menlo, Arnold & Constable, built at great expense, and which Mr. Edison bought last year from them. The main buildings consist of three massive structures, each 100 about 100 feet long by 60 feet wide, four stories high, and built of brick in the most substantial manner. Mr. Edison hopes to begin work in them soon time next month. They are supplied with every device for experimental work which the scientific mind can imagine. The buildings will be heated by steam and lighted by electricity.

The engineer will be supplied to all the machinery. Every accurate laboratories will be fitted up with every known apparatus for experimental work in physics or chemistry, and scores of experts, brought from all parts of the world, will attend daily to place their knowledge at Edison's disposal.

In the contests with which the enormous new to be stocked, there have been thousands of thousands of dollars spent, and if Edison does not have every needful article used in his science, it will not be the fault of his assistants. He has given directions to go through had a dozen weeks on chemistry, physics and mechanics, and make a list of every article required. For instance, in turning over Watts' Chemistry one comes across the materials at every page, and heard of containing the most complicated chemical laboratories all these Edison must have if he can obtain them. He will have every kind of iron and steel, every kind of all known wood, every kind of glass, every metal in all their different forms, every stone, every variety of clay, chalk, every vegetable substance that may be of use. From the finest the Arctic regions to the plant grown in the Amazon. Half-a-dozen times in Sidney's life his work has been brought to a standstill by the lack of even one material wanted in order, but which could not be obtained without long delay and great cost. If a battery used to Japan to get the bamboo fibre with which he makes his carbons for his lamps. As yet he is interrupted in his work upon the apparatus for generating electricity directly from heat, by the impossibility of finding nickel in sufficient quantities in the country to be rolled in England, and has had to succeed operations until the metal can be had. Any museum he may require from almost exhaust of material can be seen by this wonderful collection, the list of which already reaches 5,000 items, to provide against annoying delays.

When found yesterday morning in the laboratory of his lamp factory in Newark, from which, 4,000 lamps a day are now turned out, Edison said that the commercial phonograph is now the most interesting thing in the world to him, although it is perfectly finished, and tools are being made for its manufacture upon a large scale. The apparatus is so simple, so effective, and so immediately useful that he is certain of its rapid introduction into business—for more certain than he was of the universal adoption of the telephone as a business instrument. Edison said of his newly finished phonograph: "You know that I finished the first phonograph more than ten years ago. It remained more or less of a toy. The germ of something wonderful was perfectly distinct, but I did it impossible with it, was when the circumstances happened commercial importance. Now everything is overboard for that. Nevertheless, the phonograph has been more or less constantly in my mind ever since. When reading the prolonged work upon the light, my brain would revert almost automatically to the phonograph. Since light has been finished, I have taken up the phonograph, and after eight months of steady work, have made it a commercial invention. My phonograph I expect to see in every business office. The first five hundred will, I hope, be ready for distribution about the end of January. Their operation is simplicity itself, and cannot fail. The merchant or clerk who wishes to send a letter has only to set the machine in motion, and to talk in his natural voice and at the usual rate of speech into the mouthpiece. When he has finished, the sheet, or 'phonogram,' as I call it, is ready for putting into a little box made on purpose for the mails. We are making the sheets in three sizes—one for letters of from 600 to 1,000 words, another size for 2,000 words, another size for 4,000 words. I expect that an average user will not be much below the four-inch sheet, combining the phonogram boxes to be sent at a small rate in letter paper.

"The receiver of a phonogram will put his sheet in position and the message will be given over correctly, more distinctly than the best-spoken words ever were spoken. The tones of the voice in the two phonograms which I have finished as to be perfectly reproduced under the notion of best, and Edison has perfectly succeeded in that one thing. The two tones have been which he wrote in the receiving of an iron which came to him from Europe in the last winter. He is not quite sure that it will answer in a practical cotton-picker, but he has faith enough in it to make the experiments. He will say yet say in what consists the essential features of his proposed machine. The last week which he proposes to undertake very soon is to run the Greenstreet-cars upon an electric system which he says will not need any overhead wires or underground conduits, both expensive and troublesome necessities of all existing electric railways. He is confident that he can do this, and I may hear him upon the first working models.

Scientific American No 9
Oct 29 1887.

Edison's New Phonograph.

A reporter of the *Evening Post* lately interviewed Mr. Edison, and obtained the following interesting particulars:

When found in the laboratory of his lamp factory in Newark, from which 4,000 lamps a day are now sent out, Edison said that the commercial phonograph is now the most interesting thing in the world to him, although it is perfectly finished, and tools are being made for its manufacture upon a large scale. The apparatus is so simple, so effective, and so immediately useful that he is certain of its rapid introduction into business—for more certain than he was of the universal adoption of the telephone as a business instrument. Edison said of his newly finished phonograph: "You know that I finished the first phonograph more than ten years ago. It remained more or less of a toy. The germ of something wonderful was perfectly distinct, but I did it impossible with it, was when the circumstances happened commercial importance. Now everything is overboard for that. Nevertheless, the phonograph has been more or less constantly in my mind ever since. When reading the prolonged work upon the light, my brain would revert almost automatically to the phonograph. Since light has been finished, I have taken up the phonograph, and after eight months of steady work, have made it a commercial invention. My phonograph I expect to see in every business office. The first five hundred will, I hope, be ready for distribution about the end of January. Their operation is simplicity itself, and cannot fail. The merchant or clerk who wishes to send a letter has only to set the machine in motion, and to talk in his natural voice and at the usual rate of speech into the mouthpiece. When he has finished, the sheet, or 'phonogram,' as I call it, is ready for putting into a little box made on purpose for the mails. We are making the sheets in three sizes—one for letters of from 600 to 1,000 words, another size for 2,000 words, another size for 4,000 words. I expect that an arrangement may be made with the post office authorities enabling the phonogram boxes to be sent at the same rate as letter paper.

"The receiver of a phonogram will put it into his apparatus, and the message will be given out more clearly, more distinctly, than the best telephone message ever sent. The tones of the voice in the two phonographs which I have finished are so perfectly reproduced that one can distinguish between twenty different persons, each one of whom has his own words. One tremendous advantage is that the letter may be repeated a thousand times if necessary. The phonograph does not wear out by use; moreover I may say in a few days that I have used the same wax cylinder for a hundred years and be ready the instant I wish to do so to use it for the purpose of taking a new dictation. There will be no disputing the authenticity of the document with those who know the tones of his voice in life. The cost of making the phonogram will be scarcely more than the cost of ordinary letter paper. The machine will read out the letter or message at the same speed with which it was dictated.

"I have experimented with a device for enabling printers to set type directly from the dictation of the phonograph, and think that it will work to a charm. It is so arranged that the printer by touching a lever with his foot allows five or ten words of the phonogram to be sounded; if he is not satisfied with the first hearing he can cut out and repeat the same words over and over again, until he hears them as type. For busy men, who dislike spending time on the press, I am sure that the phonograph will be a necessity after a little experience."

"For musicians the phonograph is going to be a wonder. Owing to the extreme sharpness with which I can duplicate phonograms and the accuracy with which the apparatus gives out all musical sounds, by the early phonograph of ten years ago, which was a very imperfect and crude affair compared to that of to-day, it was always noted that musical sounds emerged out peculiarly well. A machine would withstand one *ting tar* better than wound fails. This peculiarity of the early phonograph remains. I have taken down the sounds of an orchestra, and the result is marvellously exact. Instruments can be perfectly distinguished, the strokes are sounded

NEW YORK LETTER.

EDISON'S PHONOGRAPH AND ITS POSSIBILITIES.

Coming Experiments in Flying Machines—The Wonders of Congress—The Talking Machine Exhibitions.

(FROM A SPECIAL CORRESPONDENT.)

New York, Oct. 27.—What is news, Mr. Editor? What have been the salient events of the week now in? Is it the principal news that Mr. Nicoll is running on an anti-machine ticket for district attorney, or that Capt. Isaiah has raided the Silver Grill Restaurant, or that Mrs. Jason Brown Potter has had a stage quarrel with Mrs. Langtry, or that Payton Teller Jackson of the anti-treasury has stolen $10,000 and run away to Canada with it and a female woman?

I shall not decide among them, nor shall I aspire to treat them, but content myself mainly with two or three dry items of science.

To be sure they concern the consolence and value of human life, but what is that as news compared with the arrival of the living trunne monkey? to the Adler and the City of Richmond?

The first of those items relates to the Edison phonograph as recently "doomed" by its great inventor. The account of the instrument as exhibited last night to a few of us here by a reporter of the Associated Press, the readers of the deepest men, and the simplest, is calculated to overwhelm the world generally. Edison has the reputation of not spoiling a good story in the telling when under inducement, and in the present case I learn that he speaks of his accomplishment with a modesty and recognition of scientific people that is refreshing. Still, after making all due allowance for the natural enthusiasm of the actual discoverer, it is a clear and ingenious exposition. It looks very much as if Edison had got the threshold of another epoch. He realizes the importance to that of the telephone, and thinks that both are rapidly making what each can be had.

THE IMPROVED PHONOGRAPH.

Mr. G. M. Hawkridge, the patent attorney and electrical expert, tells me that he understands the improvements to be in the plan which receives the impressions from the sound-needle; that instead of receiving them, as they did, on wax used, this substance is not fit for good results. Experiments are now being made in connection with pieces of paper coated with wax, but for the present the records on a plate that would resist pressure and heat. Celluloid has also been used, and this is probably the substance which Edison will employ when he has the most available.

But can the human voice be printed in print-ing? Why not? Why not a museum of a last concert or a final word will be imparted in such a way that it will be repeated endlessly at will? The wear goes, "Children, words can never die,"—science and science only can never die,—and so as I say, Edison has made a step which on this and the September meeting of the American Association for the Advancement of Science, caused them to distinguish rare with rapidity. Nickel does not attain so high a degree of magnetization as iron, but it loses it more rapidly under the action of heat, and Edison expects better results from it than from iron. The cotton picker upon which he is at work is the result of an idea which came to him down in Florida last winter. He is not quite sure that it will result in a practical cotton picker, but he has faith enough in it to make the experiments. He will not yet say in what consists the essential feature of his proposed machine. The last work which he proposes to undertake very soon is to run the Orange street cars upon an electric system which he says will not need any overhead wires or underground conduits, both expensive and troublesome necessities of all existing electric railways. He is confident that he can do this, and is now busy upon the first working models.

[illegible] rose by some of the keenest and best-balanced [illegible] wise, and the scientific world expects the [illegible] soon to be solved now at any moment. It [illegible] the order day. The Boston Advertiser [illegible] the subject sedulously, taking as a text the recent experiments of Professor Richard A. Proctor, and on the subject of this newspaper may to later prepared then less discriminating persons to learn that there are hard-headed and responsible capitalists who are [illegible] accomplish their intention when a Nicoll will follow! For did you ever see a man so anxious that success is serious incurable would mean? It would simply bring about a new heaven and a new earth. Now it would never be accomplished, for example, for it would be difficult to patrol the former to the height of the aeronaut-ships.

THE ALUMINUM WHEEL.

The further machines I speak of are to be propelled by that new aeronautic sail-of-sail-work [illegible] Edison, the aluminum wheel. But what is the plan of construction in it do not say, except if we could but reduce aluminum easily and cheaply, that would settle the business at once! This is perhaps the greatest "if" that bother [illegible] of the age. There are to be a metal as strong as steel and as light as wood, and filling the world with its abundance, and yet it is not known how it is now at an expense which deserves it as a commercial machinery. The largest block of it in the world, I believe, is the triangular cap which crowns the apex of the Washington monument. It is not large, but it is there, and it is there to warn us that aluminum must have its day. Most very soon we hear a shout of "Eureka!" but somehow the mind refuses to assume and easily as before. I could tell a very good story about the discovery of it which, but I specify, that the circumstances of all will no the actual discovery of the process by which it is made and how it is worked. Time will show, and we shall soon be flying through the air, and doing about as we please with better [illegible]

74 Herald, Boston, Mass. Nov. 28 '77.

THE new phonograph that Edison has just perfected is the greatest wonder of this age of wonders, if it is all that the inventor claims. A person can talk or sing and make any other sound of the voice into one of these instruments in motion and the whole is faithfully recorded, so that it can be reproduced by a duplicating instrument as many times as desired, and can be preserved a thousand years. The tones of the voice, and even of the different instruments of an orchestra, are exactly reproduced. It may yet be possible for us to hear a speech of Gladstone in the very tones in which it was uttered, without ever going to England or his coming to America. The debates and speeches in Congress can be more fully and accurately taken down than by any shorthand reporter and reproduced in every hamlet in the country. It was ten years ago that the first instrument was invented, and all this time the inventor, has been at work to perfect the invention, the hardest task being to proclaim the power. The duplicating instruments are said to be very cheap.

Wheeling W. Va. Nov. 28, 77.

THE PERFECTED PHONOGRAPH.

Mr. THOMAS EDISON has "got" a new wrinkle into his phonograph, the "wonderful speaking machine." He has, after assiduous work, perfected it so that it will be a very useful adjunct to the business offices. He told a reporter the other day that the commercial phonograph, which he has succeeded in perfecting, is the most important of his inventions. He says that the apparatus, is so simple, so effective, and so insignificantly useful that he is certain of its rapid introduction into business—far more certain than he was of the general adoption of the telephone as a business instrument.

Mr. EDISON says that the operation of his commercial phonograph is simplicity itself, and cannot fail, and he expects it to be part of the equipment in every business office. According to the inventor, the merchant or clerk who wishes to send a letter has only to set the machine in motion, talk in the natural voice and at the usual rate of speed into the receiver. When he has finished the sheet, or "phonogram," it is ready to send through the mails, where his correspondent places it in a phonograph and grinds out the message much more distinctly and accurately than messages can be sent over the telephone.

Mr. EDISON says that one tremendous advantage is that the message may be repeated a thousand times if necessary. Moreover, printers may set up copy from the phonograph, and people may enjoy concerts by means of the same invention, and what is once acted is practically indestructible. Mr. EDISON says:

My first phonograph, as you remember, consisted solely of a tinfoil carrying this foil, and provided with a diaphragm-point properly arranged to scrape or indent the tinfoil. The cylinder was turned by hand. In the new instrument there is far more complication, but altogether different results. My speaking machinery consists of a small electric motor, run by a very few cells. Strange to say, I have found more difficulty in getting a motor to suit me than any other part of the apparatus. I tried every form of clock-work and spring motors, but found them untrustworthy and noisy. The motors I am now making are absolutely steady and noiseless. There is no new part of the apparatus, the tools for which I am not making on a large scale here, which is ready to get out of order or work in an incertain manner. The two fields of phonographs are practically exactly what I intend to offer for sale within a few months.

What next?

Post-Dispatch, St. Louis Nov. 6. 77.

WIZARD EDISON TALKS.

HE TELLS WHAT HIS FORTHCOMING PHONOGRAPH WILL DO.

More Wonderful than the Telephone—To Be Ready in January—Almost Incredible Claims—Writing This a Year to Become a Lost Art.

Special Correspondence of the Post-Dispatch.

NEWARK, N. J., November 1.—Thomas A. Edison was found yesterday by the POST-DISPATCH correspondent in the laboratory factory but not at all disturbed by the criticisms of some scientific skeptics, who doubt that his coming phonograph will be able to do half or a quarter of what he claims for it. In answer to a few hundred questions, more or less, Mr. Edison said:

"Further, I am wrong in telling you anything about my phonograph, because what I claim for it is so extraordinary that I get only ridicule in return. I am so confident that when the apparatus appears it will dispel all doubts as to its workings and novelty, that I will be silent for the present to ignore all idiotic criticism and keep at my work regardless of the storm which I have been raising by telling of how good that work was such a thing as a perfected phonograph is existence. I am sure that when I settle down many doubts that I have entertained as well as I say I have, they will admit that there is nothing at all impossible in what I claim, and that the germ of the perfected phonograph, should such a thing appear, is a very clear in my old toy of ten years ago, which was exhibited all over the country, and was then acknowledged to be one of the wonders of the century. Just consider for a second what my old phonograph is, and think how little needed to be done to bring it to a working instrument. With my roughly-constructed instrument of 1877 I reproduced all sorts of sounds, getting back from the phonograph something like the original sound. Of course, you had to put into the tilling, and the reproduction of conversation was often accordingly of a caricature of the original. Nevertheless, to obtain a result that could be understood was doing wonders, and most people who remember my exhibitions will admit that while I did not produce a commercial machine I made a very interesting and creditable attempt, and my whistling and singing phonograph was a wonder.

THE FIRST INSTRUMENT.

"There were all sorts of objections to detail to my first instrument. It ran only a few hundred pounds; it cost a mint of money to make; no one but an expert could get anything intelligible back from it; the record made by the little steel point scratching on the foil lasted only a few times after it had been put through the phonograph. I myself doubted whether I should ever see a perfect phonograph, ready to record any kind of intelligible speech and to give it out again intelligibly. But I was perfectly sure that if we did not accomplish this, the next generation would. And I stopped the phonograph and went to work upon the electric light certain that I had sown seed which would come to something. For ten years the phonograph has been constantly on my brain automatically and unconsciously, and I would turn it over and over mentally every night when I went to think about. When I started talking about it, when traveling, when I was in the laboratory, I would turn it over and over and 365 days say now and then experimenting. Night months and I began to see my way clear to it. Then, and a month ago I stopped because really was no further improvement to be made. It is now complete, practical, cheap, effective, not liable to get out of order, and in fact everything that I ever claimed it does, everything that I ever claimed it could do, everything that I ever claimed it would do. THE PHONOGRAPH WILL SPEAK AS MUCH AS

anyone on the continent's desk "before the size of the desk, as a typewriter does. It will work automatically by a small electric motor, which will be started by the touch of a button, and will dictate, and stop and start at any point by the touch of a finger.

"Suppose a business man wishes to write a letter; he calls another to the mouthpiece of the phonograph to take, and starts the machine. He then dictates his letter in the ordinary manner, uttered. When he is done he pulls out the cylinder, and it is ready to be put in the mail. The receiver places the cylinder in a similar phonograph, touches the button, and the letter is dictated. Instructions will also be given about the letter. In some places distinct, clearer, more characteristic speaking will be required than any telephone can, or ever will be used. The phonograph would of a bad, loud voice, particularly if the person speaking does would not always want to talk, because persons can hear all over one office. In signing for goods at railroad stations and express offices the phonograph would save time for clerks' and customers' fingers. Instead of writing his name, the receiver would simply call into the phonograph his name, and the record would be taken off by the clerk. Many other uses will suggest themselves.

YOUR EXPECTATION.

"Now for my expectation. I expect that this machine will be found in the office of every business man, and particularly in the office of the lawyer and the reporter of business will never think of losing time by writing when they can dictate to a phonograph, should such a thing appear, in very clear in my old toy of ten years ago, which was exhibited all over the country, and was then acknowledged to be one of the wonders of the century. Just consider for a second what my old phonograph is, and think how little needed to be done to bring it to a working instrument. With my roughly-constructed instrument of 1877 I reproduced all sorts of sounds, getting back from the phonograph something like the original sound. Of course, you had to put into the tilling, and the reproduction of conversation was often accordingly of a caricature of the original. Nevertheless, to obtain a result that could be understood was doing wonders, and most people who remember my exhibitions will admit that while I did not produce a commercial machine I made a very interesting and creditable attempt, and my whistling and singing phonograph was a wonder.

ELECTRICITY BOXED.

New York, May 31, 1881.

To THE EDITOR OF THE HERALD:—

The main deep-rock resource published in the HERALD concerning the transmission of stored up electricity in a hand-up battery announces a discovery of positively high importance in its bearing on the electric light problem. One of the great difficulties in the way of cheaply furnishing electricity for lighting purposes was its impossibility of storing the current. A "motor" of electricity cannot be made during the day accumulated in reservoirs to be drawn off as wanted at night—as may be done with gas—but, on the contrary, electricity must be produced as it is needed. The consequence of this is that when a company undertakes to supply a given district it must manufacture and send through the wires enough current to supply all the lamps therein, even though only a fraction of the number of the lamps be connected with it. Of course this wasted power is an important item in the cost of electric illumination, first to produced ultimately to consumer.

Mr. Camille Faure, and lately following him Mr. Gaulin Faure, with what appears to be a feasible way of storing up electricity. It stands to understand that this is not a plan for gaining incessant power, as might be inferred from the statements of the London *Times'* correspondent quoted in the despatch, because nothing is more certain than that not one jot more power can be got out of any contrivance that is put into it, HENRY KEELY & Company apparently in the contrary notwithstanding. But one for accumulating weak energy over a long time and delivering the accumulation in a short time, so that a small force may be adjusted to work through passages—and into places—where only an extended series of weaker forces can now go. In this material "secondary element" consists of two strips of lead coiled in a spiral form, with a porous sheet of felt or flannel between each fold. By means of a current from a Grove or Bunsen cell, or from a dynamo machine, the lead in the positive element is changed into peroxide, a sea of acids and impurities lead is formed on the surface of the metal, and the negative element is changed into spongy lead. Either by a reversal of the current or connection in reverse, the peroxide of lead is changed back to lead, and the spongy lead to peroxide. Thus the chemical action is reversed, and the battery is ready again to give out the energy that stored in capable of doing it was first put into it. A battery weighing 4 pounds, and provided with lead, kept in one cubic foot.

The bearing of this invention on the economical problem of electric lighting is that the accumulation of weak energy during many hours may be concentrated on a single hour, or even minute, when the demand for that energy may happen to be greatest, thus overcoming the objection to the practicability of electricity for illuminating purposes will be considerable. ON M. C. FAURE'S SECONDARY BATTERY.

The researches of M. Gaston Planté on the polarization of voltameters led to his invention of the storage cell, composed of two strips of lead immersed in acidulated water. These cells accumulate and, so to speak, store up the electricity passed into them from some outside generator. When the two electrodes are connected with any source of electricity the surfaces of the two strips of lead undergo certain modifications. Thus, the positive pole retains oxygen and becomes covered with a thin coating of peroxide of lead, while the negative pole becomes reduced to a clean metallic state.

So long as the secondary cell is separated from the primary cell, it forms a veritable voltaic battery, for the symmetry of the poles is destroyed, and one is ready to give up oxygen and the other eager to receive it. But when the poles are connected, an intense electric current is established, but it is of short duration. Such a cell, having half a square metre of surface, can store up enough electricity to keep a platinum wire 1 millim. in diameter and 8 centims. long, red-hot for ten minutes. M. Planté has succeeded in increasing the duration of the current by alternately charging and discharging the cell, so as alternately to form layers of reduced metal and peroxide of lead on the surface of the strips. It was soon that this cell would afford an excellent means for the conveyance of electricity from place to place, the great drawback, however, being that the storing capacity was not sufficient as compared with the weight and size of the cells. This difficulty has now been overcome by M. Faure; the cell as he has improved it is made in the following manner:

The two strips of lead are separately covered with minium or some other insoluble oxide of lead, then covered with an envelope of felt, firmly attached by rivets of lead. These two electrodes are then placed near each other in water acidulated with sulphuric acid, as in the Planté cell. The cell is then attached to a battery so as to allow a current of electricity to pass through it, and the minium is thereby reduced to metallic spongy lead on the negative pole, and oxidized to peroxide of lead on the positive pole; when the cell is discharged the reduced lead becomes oxidized, and the peroxide of lead is reduced until the cell becomes inert.

The improvement consists, as will be seen, in substituting for strips of lead masses of spongy lead; for, in the Planté cell, the action is restricted to the surface, while in Faure's modification the action is almost unlimited. A battery composed of Faure's cells, and weighing 250 lbs., is capable of storing up a quantity of electricity equivalent to one-horse power during one hour, and calculations based on facts in chemical chemistry shows that this weight could be largely decreased. A battery of 24 cells, each weighing 14 lbs., will keep a strip of platinum ¼ths of an inch wide, 1-32nd of an inch thick, and 5 feet 10 ins. long, red hot for a long time.

The loss resulting from the charging and discharging of this battery is not great: for example, if a certain quantity of energy is expended in charging the cells, 80 per cent of that energy can be reproduced by the electricity resulting from the discharge of the cells; moreover, the battery can be carried from one place to another without injury. A battery was lately charged in Paris, then taken to Brussels, where it was used the next day without recharging. The cost is also said to be very low. A quantity of electricity can be produced, stored, and delivered at any distance within 3 miles of the works for 1½d. Therefore these batteries may become useful in producing the electric light in private houses. A 1250 horse-power engine, working 4 dynamo machines giving a continuous current, will in one hour produce 1000 horse-power of effective electricity; that is to say 80 per cent of the initial force. The cost of the machines, establishment, and construction will not be more than £40,000, and the quantity of coal burnt will be 2 lbs. per hour per effective horse-power, which will cost from 1½d. to 2d. The apparatus necessary to store up the force of 1000 horses for twenty-four hours will cost £48,000, and will weigh 1500 tons. This price and these weights may become much less after a time. The expense for wages and repairs will be less than 1½d. per hour per horse-power, which would be £24 per day, or £8800 a year; thus the total cost of one-horse-power for an hour stored up at the works is 3½d. Allowing that the carriage will cost as much as the production and storing, we have what is stated above, viz., that the total cost within 3 miles of the works is 7½d. per horse-power per hour. This quantity of electricity will produce a light, according to the amount of division, equivalent to from 5 to 30 gas burners, which is much cheaper than gas.—*Chemical News.*

Scientific American (Combined), Mass.)
June 4, 1881.

THE announcement is made of an improved method of storing electricity, by M. Camille Faure, of Paris, the *London Times* asserting that "a box of electric energy nearly equivalent to a million feet, contained within less than a cubic foot of space, intact and potential, has been transported from France to Great Britan."

Sir William Thomson is said to have given some endorsement to the discovery, and tests and measurements are in progress at the laboratory of the Glasgow University.

The principle involved in M. Faure's discovery is understood in this country, and the possibility of its general correctness is conceded. The language employed in the announcement is rather equivocal, and the misuse of scientific terms render the exact extent of M. Faure's discovery a matter of some doubt.

We gladly welcome any progress in electical science; but as the necessity for storing electrical energy is of value only in very rare cases, the practical usefulness of M. Faure's discovery must be limited in extent.

MR. EDISON has courteously responded to a request on our part, to offer his opinion on M. Faure's discovery, and we take pleasure in placing before the readers of "SCIENCE" his reply, received since our own notes were in type.

To the Editor of "Science."

DEAR SIR: The Faure battery is an improvement on the Planté battery.

Planté was, I think, the original inventor of the battery which bears his name, invented some years ago for the purpose of storing up electricity.

Faure has simply made a Planté battery, by some means reducing its resistance, and thus reducing the percentage of loss. This is all there is in it.

Some two years ago I patented and applied a method for using the Planté battery in connection with electric lighting. Yours truly,

THOS. A. EDISON.

STORAGE OF ELECTRICITY.—A new secondary battery, of greatly enlarged capacity, is now attracting attention in Paris. It is the invention of M. Faure, but is confessedly a development of the well-known secondary battery of M. Planté, which is formed of sheets of lead immersed in acidulated water. The latter gains in capacity as the process of charging and discharging is repeated, through increasing thickness of the layer of peroxide of lead that is slowly formed by the currents. M. Faure has conceived the idea of coating the two electrodes with layers of minium, or the red oxide of lead, and by this means the capacity is greatly increased. The Faure battery is stated to have forty times the power of accumulation of the Planté. A battery weighing 75 kilogrammes will develop 75 kilogrammètres, or one horse-power, during one hour. As to the source of the action, the electric current appears to change the minium to peroxide on the positive electrode, and to reduce lead on the negative. In discharging, the reduced lead is oxidized, and the peroxidized lead is reduced. The battery was lately exhibited by M. Reynier to the Society for the Encouragement of National Industry. There were 24 couples, weighing seven kilogrammes each, connected to a Siemens machine of medium size; these furnished a work of 47 kilogrammètres, which is about a third of M. Reynier's figures; but the conditions were unfavorable. Next in hand of platinum, three mètres long, 12 millimètres broad, and 4-tenths of a millimètre thick was made to glow; then two incandescence-lamps were lighted. The superiority to the Planté battery was well demonstrated. Some competent physicists speak hopefully of M. Faure's battery as a means of distributing electricity to any house or workshop independently of others that may be supplied, and free from the drawbacks of a system of accumulation. The method is also regarded as very promising for domestic electric lighting. A company, it may be added, has been lately started in Paris by M. Philippart, for obtaining force and light by electricity, by combination of the Reynier and Faure batteries. M. Hospitalier has pointed out the expensiveness of charging the Faure battery with electricity from chemical action.

SECONDARY BATTERIES.

THE important part that secondary batteries will eventually play in electric lighting, renders any items in connection with their construction of great interest. As will have been expected, several patents have been recently taken out, and many others are awaiting publication. Of some of the devices we are enabled to give a brief description, which may be of interest, though there is reason to believe that later forms have superseded them. As we mentioned some time ago, Mr. Sellon has taken out several patents for secondary batteries, and as the development of that invention will form a feature in the electrical history of the nineteenth century, we give a short account of some of his various specifications. In the first of these he mentions, that in manufacture of batteries with lead, he describes the use of perforated plates, electro-roughened, serrated, or indented, composed of lead, platinum, or carbon, upon, in, or against which are held films of spongy lead, or salts of lead, or other suitable substances. In the drawings accompanying this specification, Mr. Sellon shows lead plates bent so as to form a series of dovetails over the surface, or serrated like the teeth of a saw, both being perforated with numerous holes, in which and in the folds of the serrations or the dovetails, the active material can be packed, the object being to get as much as possible of that into the smallest compass. Five days after that specification was deposited, Mr. Sellon appears to have found that a mixture of sulphate of lead with the use of magnesium had a finish resembling as the material of which the plates are to be composed. It is clear that the ingenuity of the inventor has tolerably wide scope in determining what shall be the actual form of the elements or supporting plates of the secondary battery, and it is obvious that if perforated lead plates are an advantage, they can be made up of a number of short pieces of lead tube, arranged with their axes parallel. We have reason to believe that experience has declared in favour of an alloy of lead and antimony in preference to the simple metal, and for convenience in working or for remedying any accidental damage to the active plates, plates of many perforations, reinforced by the corrugated and other devices mentioned, for the purpose of gaining surface. It will be understood that one object of these inventions is to dispense with the canvas or felt supports for the coating of oxide, because in practice it is found that nothing yet tried will long withstand the effect of the acid liquors used to excite the action. Corrugating the plates possesses an advantage in presenting greater surface in an equal space; but when felt or canvas is dispensed with, there is some flexibility of "lead-trees" forming a core and connecting the two elements of a cell. Hence, it is found advisable to corrugate the plates that any points of contact of the plates to be readily removed. M. de Kabath, of Paris, has taken out two patents for secondary batteries, the facts of which his invention being the method adopted to prevent the coating of lead-oxide from falling off. He forms a composite electrode of thin sheets of lead, folded around a thicker sheet, which acts as a support, the whole being enveloped in a sheet of parchment-paper, a substance which, having been already acted upon by sulphuric acid, is only slowly destroyed in the battery. In M. de Kabath's design the sheets are either plain or corrugated; but in all cases a thin coat of sulphate of lead is formed upon them, and the two kinds of alternate plain and corrugated lead, packed between stout lead covers held together by indiarubber bands, the whole being immersed in the liquid with holes. M. de Kabath has also taken out a patent for a method of regulating the discharge of secondary batteries (September 20th, 1881). That is accomplished by increasing or diminishing the depth of solution in the battery-cell by means of a tap moved by magnets actuated by a relay. Thus when the current in the main circuit decreases, the spring of the relay moves the index and puts into action the magnet controlling the inlet of solution, so that a greater surface of the plates is immersed, and the current is increased in proportion. Similarly, if the current be too great, the tap is so turned as to cut off some of the solution from the battery, so leaving a smaller surface of plates under action. MM. Degrez and Carpentier have also obtained a patent (September 27th, 1881) for distributing and regulating the transmission of electrical power, in which they use two secondary batteries, so connected by means of a commutator that while one is being charged the other is giving out current; but as they do not specify any form of battery, the claim is only for the details of the arrangement.

Secondary batteries having some really novel features, have been patented by Mr. A. Watt, of Liverpool (October 1st, 1881). He uses the lead-plates, but coats them with a mixture of caustic hydrate, manganese dioxide, and sodium chloride, or preferably with what is known as "Weldon mud," mixed in equal parts with manganese dioxide. The positive plate is a sheet of hammered lead, and in a solution of salt or of manganese one be employed, it soon coil, as the sulphate decomposes and covers the action with peroxide of manganese. Another form of battery consists of alternate layers of carbon and granulated manganese dioxide mixed with granulated carbon, preferably in equal volumes, or of lead and manganese dioxide or layers arranged as follows: — MnO_2, $Pb|O$, $MnO_2|O$, $Mn_2O_3|O$, $Pb|MnO_2|O$ and so on, or Pb, $MnO_2|O$, Pb, $Mn\ O$, $C|O$, the vertical bars representing porous diaphragms. The exciting liquid is salammoniac, common salt, or dilute sulphuric acid. A convenient form of cell consists of an ordinary battery jank divided down the centre by a porous diaphragm. The charged porous pots, fresh or exhausted, of Leclanché cells, may often be used without further preparation than emptying out the exhausted of the solutions. If one pot be fresh and the other exhausted, the couple is charged and ready for work. Another modification consists of a porous pot containing a plate of carbon charged with a mixture of manganese dioxide and carbon or coke, in a state of coarse powder, and placed in a lead vessel containing dilute sulphuric acid, the space between the pot and the leaden vessel being filled with a mixture of manganese dioxide and carbon or coke, or simply with granulated lead.

Another secondary battery, which is based on the action of chlorine on copper, has been patented by Mr. A. P. Laurie, of Edinburgh (October 4, 1881). The cell is made up of a thin plate of copper, coated with a paste of cuprous chloride, and wrapped in parchment-paper; that, together with a plate of zinc, is placed in a solution of chloride of zinc, and the two being connected a current is set up, which continues until the cuprous chloride is reduced to a state of spongy copper. The zinc plate is then withdrawn, and another one put into the cell, which is then ready for charging. The action of the chlorine on the spongy copper can be regulated by means of copper plates placed over the spongy coat, and connected to the copper plate. These notes, together with those given in p. 413, and elsewhere in the last volume, will serve to convey some idea of the different methods of making up secondary batteries. It is tolerably obvious that, but for its weight, lead would be the only metal exploited upon, its advantages being so considerable, especially in the shape of cost; where, however, flexibility is desired, it is probable that Sutton's some modification of the copper-lead cell will be utilised. Possibly, the researches of Dr. Gladstone and Mr. Tribe may lead to the discovery of something more valuable than is yet available.

several additions made to the meter to increase its utility, and appears to cover every mode by which electrolytic action can be practically used to register the quantity of electricity passed into a circuit.

The original idea of plates of metal acting alternately as anode and cathode, reversing the direction of the current by the weight of the metal transferred, and registering the number of reversals, is still the basis of the instrument; but all the mechanical modes of supporting the plates by springs or balance-beam are done away with. A single moving plate is used, which floats in the liquid like a hydrometer, and which sinks or rises in the liquid exactly in proportion to the weight of metal added to or taken from it. As the quantity of metal which serves as the measure of the electric quantity is added to the electrode, it sinks till the limb is raised, when a contact is made, which sends a

receives ... metal while the other dissolves, the centre of gravity is displaced, and the cylinder rotates on its axis, and by its motion records the electricity passing. The idea is no doubt promising; but how it will perform in practice, would probably require to be determined by actual trial.

But another modification appears to offer considerable promise of utility in connection with electro-metallurgy. The motion of the electrode is transferred to an index which traverses a scale, showing the subdivisions of the interval between reversals. This scale may be made to show ounces of silver or gold deposited during each interval, and a shifting contact is placed over each of these divisions, so that, if a silvering vat contains articles on which it is desired to deposit five ounces of silver, the stop would be adjusted at that point. When the indicator reached this spot it would touch the stop, and send a current into a con-

... This new patent contains also

... ated in a very simple manner by the reverser. The moving part of this carries a small wheel, upon which lies a lever also carrying a small wheel, and when the reverser is at rest these wheels are in close contact. The end F of the lever, therefore, lifts the lever by the action of the two wheels passing each other, and each such raising of the lever moves the locking-train one tooth.

An automatic heating arrangement, which may be applied to various other uses, is employed to prevent the solution from being frozen. It consists of a coil of fine wire inclosed in the space between two glass tubes placed vertically in the liquid. When this wire is heated by the current, a stream of warmed liquid will flow out, and thus warm the liquid in which the cells are immersed in a very economical manner, and other means of effecting the same object will suggest themselves to any one conversant with the subject.

The current passing through the heating-coil is automatically regulated by a thermometer-switch, which closes the circuit when the temperature falls to a fixed degree.

The influence of change of temperature upon the liquid and metal of the meter circuit, by which the latter is guarded against by balancing it with a compound of graphite and German silver, is adjusted that the variation is equal in both circuits; but the core taken by the various designs shown in the specification, appears to indicate that the intention is rather to do away with the complication of shunts by sending the whole current into the meter-plates which will no doubt give less scope to the suspicions of consumers.

There is another mode of action shown which is based on a new idea, which may, however, be seen fourteen years ago employed in a reversible electrical motor, in which the motion was produced by the metal in transference from one electrode to the other without reversal; but three plates and this metal, though they do the work, have nothing to do with the measuring. The current in this case does not require weighing between faces do not require weighing between them, but possess them to a cylinder forming one of the bearings. As the ends of the cylinder

ments must be preferred, to my mode of merely weighing a deposit at intervals.

EDISON'S CURRENT METER AND OTHER IMPROVEMENTS.

A MEANS of measuring the quantity of current passed along a given wire is as much a necessity of the present system of lighting by electricity as the gas-meter is to the existing system. It may be remembered that Mr. J. T. Sprague patented a simple device for calculating the quantity of current by the amount of copper deposited in a decomposition cell, and it so happened that Mr. Edison patented, or applied for a patent for, an invention which is practically identical with the first form of the invention, and described in the specification (1550, 1881) the new meter indicates a correct result with a smaller current than was required by the copper cell. The invention has been on view at the Crystal Palace, and was briefly described by me some time ago. It consists of amalgamated zinc electrodes in a solution of sulphate of zinc, and the meter is charged to the maximum of current it is to record by the increase in weight of the zinc plates, which are taken out from the electrode, and the plates—zinc, being deposited on the opposite—ad ed on the other. According to the specification, a lower rate of speed is to be given to the plates, which also is to be accomplished by clock-work or electric motor; but according to the description of the process given by those connected with the invention, the plates are coated with chemically pure zinc, so as to reduce local action to a minimum, and they are then amalgamated. The plates are about the size of ordinary sash sashes, 30in. by 18in.; they are a quarter of an inch thick, and are kept apart by a little strips of ebonite about a quarter of an inch thick, and clamped together by ebonite screws passing through the centre of their lengths. The depositing cell is separated from a shunt from the leading conductor of the house or other circuit in which it is desired to measure the amount of current consumed,—a resistance being placed in the

lice as about a small definite portion of the current through the meter. In the wire leading to the latter is another resistance in compensation for the effects of change of temperature. This resistance is formed of copper wire, the electrical resistance of which increases with a rise in temperature, while that of the solution in the cell diminishes. A sufficient length of copper wire is, therefore, put in the circuit to equal the loss of resistance in the cell, and the arrangement is thus permanently compensated for temperature. Arrangements are, however, made to prevent the temperature of the apparatus (including the compensating resistance) for which it is reached on Fahrenheit, wherein into circuit, the heat from which quickly raises the temperature of the box in which the meter is enclosed. When not in current is being worked on a three-ranged beside that shown, thereby rendering the establishment of a counter-current and the recognition of the solution. The practice it is proposed in use two meter-cells placed in a cast-iron box so connected that one replaces at a greater rate than the other, but in some proportion. One of the cells would be examined monthly by the ordinary officers of the company; the other would be left in the cells entirely at superior officers, and would be examined quarterly. It is proposed that the by-cell on coming to "take the meter," should remove one of the cells, and replace it by a fresh one, the cells so removed being taken to the local office, and the plates carefully weighed after being protected. The difference in weight will be calculated in values, suspicion of waste, or whatever term may be used to denote the amount of current consumed, and the bill will be made out accordingly. Whether it will be paid scrupulously remains to be seen, for it is difficult to see what check the householder will have on the Electric Light Company, and remembering the perennial misery which prevails in most of the toll-bars, which every householder must avoid if he can, we are afraid great charges will be made when consumers have no choice at all. The upper cell, with the tipping plate, which registers the current consumed on the "make" side of the galvanometer, is considered sufficient for use in the houses of customers, but will require a further.

Another of Mr. Elliott's improvements is a method of regulating the gravitative force of the chronometric machine. In this invention (1,752, 1881) a device is adopted for diminishing the mass of the pulse imparting the cause of the train-impetus. The electromotive force is kept constant by means of an electrolytic cell, which sets upon a central block, fixing a central spearing in the centre of the pulse. In Elliott's chronometric escapement machine, this method is to control block drawn into the hole in the pulse by the electro-magnet, and forced out by a spring and its heavy weight, can be easily adapted, but for other purposes the pulse to connect the block to the pulse.

Another invention recently patented relates to a method for establishing the electromotive force of a current from secondary batteries by reference to the same current from time to time, so as to keep up the electromotive forces in the consumption circuit; such as the arrangement cannot be explained without diagrams, we must refer those interested to the specification, No. 4153, of 1881.

WILLOUGHBY SMITH'S INDUCTOPHONE.

WE mentioned in the "Scientific News" last week that Mr. Willoughby Smith had, in the course of some investigations into the phenomena of telephony, made a remark with discovery—if, indeed, it may be so called—that the magnetic lines of force from a flat coil of insulated wire could be made to act upon it, would produce the same musical note as that given by a tuning-fork used as a make-and-break contact in the circuit with the coil, although there is no audible connection between the fork and the coil. The apparatus, which has recently put taken a definite form, has been called the inductophone, a name which satisfactorily expresses the nature of the phenomena. It consists of a bound, on which is mounted horizontally a tuning-fork, one arm of which carries a light platinum contact piece normally pressed against the point of a platinum screw placed on one side of the fork. The fork is actuated by a small electro-magnet, which, when the current is passed, maintains the vibrations of the fork indefinitely. The connections are so arranged that the current alternates, when the fork is vibrating, between the make-line and a short circuit, and in the main circuit is placed the flat disc of coil, made up of insulated wire, rather fine, laid between two pieces of ebonized wood in a frame so as to resemble in shape an ordinary bedroom looking-glass. One end of the coil is connected to the battery—Mr. Smith used a number of Leclanché elements—and the other is connected through the tuning-fork with the other pole of the battery—that is, when the fork is making contact. The fork being set in motion, the current passes through the coil of the magnet, and the make-and-break arrangement is put in full working, corresponding in number of contacts to the normal pitch of the fork. Then, if the latter is held in ordinary fork giving c.c.f., and it follows that exactly the same number of magnetic changes take place in the coil as are due of insulated wire—consequently also in the magnetic field which it creates. If, then, a thin diaphragm, a tuning-fork, or any suitable piece of iron is held in such a position that it comes within the magnetic influence of the coil, the lines of force can impinge upon it, a sound is produced which is identical with that due to the tuning-fork, although there is no physical connection between the receiver and the make-and-break. It must be confessed that this is a most curious effect, for the action is perfect, even when the transmitter and receiver are separated by a wall, and several feet of earth, the actual distance being limited only by the delicacy of the receiver. It is obvious that the greatest effect will be found in that position in which the largest number of lines of force can impinge upon the receiver of plate, and this will be found in the centre line of the coil. A call or two-notice, the intensity varying as the square of the distance. The greater the number of lines of force, and the greater the intensity of the field, the greater will be the effect produced on the receiving diaphragm. As to the distances through which the effect is produced, we are informed that experiments are being made to determine what the extreme degree of accuracy; but as it obviously depends, to a certain extent, upon the apparatus employed, end-to-end will, no doubt, be made to Paris and Berlin, etc. Meantime we have given sufficient particulars to enable experimenters to take up the study of a very interesting phenomenon.

ELECTRICAL ACCUMULATORS, OR SECONDARY BATTERIES.*

By Prof. Carus J. Lenox, B.Sc.

(*Continued from page 256.*)

PLANTÉ and a Faure cell, though the principles underlying the construction of the two forms is different, are, generally, the plates, of formation the same thing; and consist of sheets of lead, pretty much the same with black peroxide of lead (PbO$_2$), the other with a spongy metallic state. Both are immersed in a fluid state of division and mass, of dilute sulphuric hydrogen; both plates immersed in dilute sulphuric acid. In short ordinary battery strength. Two plates in this condition exist, as explained last week, given a current sufficient to decompose a wire, the positive current dashing along the wire from the peroxide coated plate—the spongy lead plate—the metallic—plate, and back through the liquid in the other direction; the spongy lead becoming gradually peroxidised, and the peroxide becoming less by one atom of oxygen, all the time the current lasts—i.e., until the condition of the surfaces has become the same. Temporarily or permanently the same. In ordinary cells of this kind, however, the active condition they are not continuous with sets of lead, either electricity—by which we mean mechanically—by Faure, which is then acted on by an electric current passed through the cell in the opposite direction, the current being made to enter the liquid at the plate which is to be peroxidised, and to leave it at the plate which is to be reduced. Hence the former of these plates may be perpetually indicating, for when charging the cell the current enters at it, and when discharging the cell the current sets out from it. The other plate is similarly strange — There need, therefore, be no difficulty in understanding how the cells of the storage to be connected to the motive power of the dynamo, whether the latter is supplying the current to the battery and charging it, or whether the dynamo is receiving the current from the battery and being driven by it.

Theory of Electro-chemical Decomposition.—It will be seen that work that electricity was employed through a definite by means of two opposite processes, the first being decomposition of water, the second the subsequent re-liquid is undergoing decomposition, and that every such reliable possesses a certain definite charge of electricity which it carries with it and delivers up to the electrode, either when it is set free or combines with the electrode. It was also stated that the charge of electricity possessed by a dissociated atomic particle is constant; and that dual have twice the charge, treble theirs, and so on. From these considerations it follows—as was proved by Faraday—that for a given weight of substance dissociated or liberated a certain quantity of electricity is required, a quantity which will be constant, and as we know the number of atoms liberated, the electrical charge of each, and the weight of each. Let y be the dissociation charge of a five-hydrogen or other monad atom or radicle. We do not know the value of y yet, we only know that it is proportional to the atomic weight. Let x be the weight of the atom or compound radicle formed from a combination in which n atoms of the other words, let its active atomicity have been reduced by n, or let d be the number of bonds which have been broken in the act of making it a free radicle—whichever way of expressing it is preferred—then nx is necessarily possessed of an electric charge ny.

Let Σ be the number of such atoms delivered up to an electrode in any time, then in the same time a quantity of electricity $Q = N\,\frac{x}{y}\,n\,y$ must have passed through the cell; and the weight of the substance liberated at the same time is $N = \frac{Q}{ny}$ and this M. Then

$$M = \frac{Q}{y}$$

Now, in the right-hand side of this equation $\frac{x}{y}$ is the only thing we know; we only know the relative weight of different atoms and the absolute weight of one, that of the hydrogen atom, and we know the relative weight of a hydrogen atom, and so the number ordinarily known in chemistry as "atomic weight" of any atom relatively to hydrogen, so that $x = a\,\frac{x}{y}$; then the above equation may be written

$$M = \frac{a}{y}\,\frac{x}{y}\,Q$$

Now, though neither $\frac{x}{y}$ nor y are yet known, their product has been determined by Joseph Stefan, and it is 1·0365 in C. G. S. units; in other words, the electrical charge of a five-hydrogen atom is 9565 times its weight in grammes. And the charge of any other radicle or atomic weight is

$$\frac{9565\,x}{n}$$

and with d from bonds $\frac{9565\,x}{n}$ times its weight in grammes.

Now, though neither $\frac{x}{y}$ nor y are yet known, their product has been determined by Joseph Stefan, and it is 1·0365 in C. G. S. units; in other words, the electrical charge of a five-hydrogen atom is 9565 times its weight in grammes. And the charge of any other radicle or atomic weight is and with d from bonds $\frac{9565\,x}{n}$ times its weight in grammes.

If the weight of the substances be expressed in pounds, and the quantity of electricity concerned in its liberation or decomposition be determined—as for practical purposes is rather convenient—the above number 9565 becomes 12,933, or, with sufficient accuracy in ordinary cases, 13,000. So we may repeat the above equation in an easy and simple form, a useful one—

Weight of substance acted on in ounces	=	ordinary "atomic weight" of the substance
Quantity of electricity passed through it, in Ampere-hours	=	13,000 multiplied by number of bonds broken

Whether the "substance" is the constituent which is liberated at the positive or at the negative pole, or whether it is the original compound, which is "dissociated" as all but decomposed, matters nothing. The above equation is perfectly general and universally applicable. It applies also when it is recomposition that is going on instead of decomposition.

The expression "number of bonds released or broken per molecule," is not a happy one, but the usual "change of valency" is no better, and the very simple conception is not to be expressed in best conveyed by an example. Suppose Cu SO$_4$ is being decomposed; the molecules are released when its separate from SO$_4$, hence

Weight of sulphate of copper decomposed

$$= \frac{\text{Quantity of electricity passing through it}}{63·5 + 32 + 64}$$

$$= \frac{63·5}{21,000}$$

But we might equally well write—

$$\text{Weight of copper deposited} = \frac{63·5}{21,000}$$

$$\text{Quantity of it required}$$

Take as another example the decomposition of common dilute sulphuric acid, with copper electrodes, say,

Weight of hydrogen set free	=	$\frac{1}{77}$
Quantity of it passed through cell	=	77,000
Weight of sulphuric acid decomposed	=	98
Quantity of it	=	24,000

Weight of sulphate of copper formed at the same time as the hydrogen is liberated

$$= \frac{159·5}{24,000}$$

Quantity of it

Suppose nitrate of silver is the substance acted on. Here only one bond is released per molecule, so

Weight of silver deposited	=	108
Quantity of it	=	12,000
Weight of nitrate of silver decomposed	=	170
Quantity of electricity	=	12,000

Finally, suppose the substance acted on is Pb O, the protoxide of lead, then

Weight of litharge oxidised to peroxide	=	223
Quantity of it required	=	24,000

Weight of litharge reduced to metallic lead, the same.

Thus a current of one ampère is able to oxidise on one side of a Faure cell $\frac{223}{24,000}$ lb. of litharge per hour, provided there is no waste, one ampère flowing all the time, and reduces the same amount on the other side. Or, reduced, of litharge on either weight of lead, the same formed oxide formed from a combination in which n atoms of the other words, let its active atomicity have been reduced by n, or let d be the number of bonds which have been broken in the act of making it a free radicle—whichever way of expressing it is preferred—then nx is necessarily possessed of an electric charge ny.

Let Σ be the number of such atoms delivered up to an electrode in any time, then in the same time a quantity of electricity $Q = N\,\frac{x}{y}\,n\,y$ must have passed through the cell; and the weight of the substance liberated at the same time is $N = \frac{Q}{ny}$ and this M. Then

$$M = \frac{Q}{y}$$

Now, in the right-hand side of this equation $\frac{x}{y}$ is the only thing we know; we only know the relative weight of different atoms and the absolute weight of one, that of the hydrogen atom, and we know the relative weight of a hydrogen atom, and so the number ordinarily known in chemistry as "atomic weight" of any atom relatively to hydrogen, so that $x = a\,\frac{x}{y}$; then the above equation may be written

$$M = \frac{a}{y}\,\frac{x}{y}\,Q$$

Now, though neither $\frac{x}{y}$ nor y are yet known, their product has been determined by Joseph Stefan, and it is 1·0365 in C. G. S. units; in other words, the electrical charge of a five-hydrogen atom is 9565 times its weight in grammes. And the charge of any other radicle or atomic weight is

$$\frac{9565\,x}{n}$$

and with d from bonds $\frac{9565\,x}{n}$ times its weight in grammes.

If the weight of the substances be expressed in pounds, and the quantity of electricity concerned in its liberation or decomposition be determined—as for practical purposes is rather convenient—the above number 9565 becomes 12,933, or, with sufficient accuracy in ordinary cases, 13,000. So we may repeat the above equation in an easy and simple form, a useful one—

Weight of substance acted on in ounces	=	ordinary "atomic weight" of the substance
Quantity of electricity passed through it, in Ampere-hours	=	13,000 multiplied by number of bonds broken

Whether the "substance" is the constituent which is liberated at the positive or at the negative pole, or whether it is the original compound, which is "dissociated" as all but decomposed, matters nothing. The above equation is perfectly general and universally applicable. It applies also when it is recomposition that is going on instead of decomposition.

The expression "number of bonds released or broken per molecule," is not a happy one, but the usual "change of valency" is no better, and the very simple conception is not to be expressed in best conveyed by an example. Suppose Cu SO, is being decomposed; the molecules are released when its separate from SO, hence

Weight of sulphate of copper decomposed

$$= \frac{\text{Quantity of electricity passing through it}}{63·5 + 32 + 64}$$

$$= \frac{63·5}{24,000}$$

But we might equally well write—

$$\text{Weight of copper deposited} = \frac{63·5}{24,000}$$

$$\text{Quantity of it required}$$

EFFECT OF HEAT ON A BATTERY.

A BOSCO usually recent attempts to improve the galvanic battery, Mr. Gaston Plante, the well-known engineer, Sorbier Gaudini, who describes in the results of experiments in heating batteries. He considers that his application of heat to such batteries, both from a theoretical and a practical point of view.

All the various types of batteries tried, that which is known as Leclanché was as follows:—A carbon-lined vessel containing porous tubes of terra-cotta, surrounded by the depolarising mixture, which acted as the positive electrode. A piece of carbon within the porous pot served as negative electrode. The exciting liquid was a solution of chloride of sodium, and the depolariser a superficial solution of bichromate of potash and sulphuric acid.

To the cold state, this couple gives an intense but transient current. When placed, however, on a small gas-boiler, its current increases considerably in intensity, and continues constant, with closed circuit, as long as desired if properly managed. The fluid should be regulated so as to keep the temperature of the various parts at about 100°. Experiments were also made to ascertain if the porous vessel a few centimètres of potassium bichromate, with sulphuric acid, and to the current were still weaker.

With such cars the battery will furnish a current much more intense than that produced in the cold state. The increase of intensity arises from the diminution of the internal resistance, and a notable increase of the electromotive force, as will be seen from the following:—

Battery used cold	II	II
" hot	2·10	0·81
	2·14	0·71

Here the values of E are expressed in Volt units: equal to 100 millions, or 10^8 absolute C.G.S. electromotive force, corresponding nearly to that of a Daniell element; and the values of R are expressed in ohm units equal to a billion, or 10^9 absolute units of resistance, nearly corresponding to that of a column of mercury at 0°, one metre long and 1 mm. in section.

The fact of diminution of the internal resistance is in perfect accordance with known properties relative to mixtures of liquids, and need not cause any surprise. The increase of electromotive force observes more consideration: it may, perhaps, be explained by supposing that the heat promotes the chemical action, and the current through the porous diaphragm. As to the diminution of resistance, it is evidently a consequence of the increased polarisation of the electrodes; because, with increased polarisation, the development of gaseous bubbles is facilitated.

In fine, the advantages claimed for this heated battery are as follows:—

1. A great and constant electromotive force.
2. A small and invariable resistance.
3. Economy.
4. Very composition, always presenting the same conditions.
5. Facility of adding new materials.
6. Cost comparatively slight, from the unprecedented consumption being small, the saving in that point alone compensates the greater expense of heating.

7. Lastly, a battery of six elements, formed each of an iron vessel about 6in. high, and 3½in. diameter, with all the rest in proportion, may cost about sixty lire (say, £2 8s.), and, used with heat, will give a current comparable to the maximum obtainable from a Daniell-Siemens-electric machine, modified known, which, with supports, will cost about 1000 francs. It may be noted that this battery in the cold state will have a nearly current of brief duration, as it remains a long time unaltered with open circuit.

SECONDARY BATTERIES OF M. PLANTÉ.

By A. HIGHTON-DIEUDÉ.

Secondary currents, or currents of polarisation, have formed the subject of numerous researches from the period when they were discovered, present century; but it is only within the last few years that it has been ascertained that they are capable of being applied to purposes of practical utility.

December 1, 1879.

During the last fifteen years M. Gaston Planté has been engaged upon the investigation of this subject, and, by continuous efforts and by successive stages of progress, he has arrived at results of the greatest interest—results of the nature of which we shall now endeavour to give an idea.

The reader knows that the Voltameter is an instrument in which water is decomposed by the current from an ordinary galvanic battery; in principle, it is represented one of the fundamental experiments in Physics. At the exact instant when the Voltameter has been just subjected to the action of the battery, it may be regarded as a secondary couple or element; if the two electrodes are now connected with the wire of a galvanometer the needle of the latter will be deflected during several seconds, and will show the passage of a current which grows gradually weaker and becomes imperceptible after a somewhat short space of time. This current is what is called a secondary current; it has been supplied by the battery to the Voltameter, and it is given back again by the latter.

M. Planté showed, as early as 1859, that lead is the most suitable metal for employment in secondary batteries, and he has, since that time, still further confirmed the superiority of this metal.

Fig. 2 shows a secondary element as now constructed. In a tall vessel of glass, gutta-percha, or ebonite, are placed two sheets of lead, rolled spirally, and parallel one to the other, and kept up with touching by two cords of indiarubber rolled mersed in a solution of one part of sulphuric acid to nine parts of water. The vessel is closed by a sealed cover pierced with a small hole, through which also allows the escape of any gas which may be generated during the charging of the battery. The apparatus is surmounted by a disc of ebonite, upon which are fixed two contact pieces in connection with the two electrodes; two

electrodes; for i quantity of electricity which the apparatus wou furnish is in proportion to the extent of leaden surface subjected to the action of the polarising current and covered with an active electro-chemical deposit.

It should be remarked that the particular (spiral) form of the electrodes gives an element having a large surface and a small resistance within a small space, so that one of Planté's secondary elements is equal to an ordinary element of a very unusual size; the small pattern has an active surface of 8 square decimetres (124 square inches), the large pattern a surface of 40 square decimetres (620 square inches).

The current furnished by the secondary element will effect chemical decomposition, act upon an electro-magnet, &c.; but if its intensity is measured by any of the ordinary methods, as, for example, by means of a galvanometer, it will be found to decrease gradually from the maximum spoken of above. This diminution is rather slow if the circuit has a large resistance, and if, in consequence, the electricity passes in small quantity; but it is, on the contrary, very rapid if the circuit

resistance, because the elec large quantity.

harge gives rise to an interest te battery is to all appearance d, but if it is allowed to rest th the circuit disconnected, it acquired a certain amount of again to give forth a certain city. The battery being then rst *residuum*, and again left to se, will give a second *residuum* nan the first. The latter will eral other charges can still be

ry clearly explained this pecu ulary element when it comes regard, and is at the same time case of batteries with a single ulum acquires after a certain t equal to that of the weakened , and the action then ceases or . If the battery is now allowed e itself, as happens in the case teries polarized by their own ly, once depolarized, is then e forth a current, but in the

becomes polarized afresh and so on.

Let us now suppose that the secondary element has been entirely discharged or nearly so, it can be recharged by means of the two Bunsen elements as at first; but it is worthy of notice that a fresh charge is communicated all the more quickly as the operation is performed more promptly after the discharge.

Moreover, a secondary element is all the better for having been charged and discharged a greater number of times; at first, when it is almost new, there is an advantage in polarizing the electrodes, sometimes in one direction and sometimes in the other, reversing several times the direction of the charge; but when the element is formed the greatest care must, on the contrary, be taken to charge it always in the same direction. If this precaution is neglected the time required for charging will be much increased, for the oxide of lead which may happen to remain upon one of the electrodes must be reduced and the plate, previously negative, must be oxydized. But after this operation the secondary element regains all its power and may even be said to be all the better for it.

December 1, 1879.

position all the outer electrodes are joined to one metallic bar, and all the inner electrodes to another similar bar, so that the whole apparatus is equivalent to a single element of very large surface; it is whilst in this position that the secondary battery is charged; two Bunsen elements are sufficient to effect a complete charge, the time occupied during longer or shorter according to the size of the charging cells and the extent of the leaden surfaces to be polarized. In the second position of the commutator, the exterior electrode of each element is connected to the interior electrode of the next element, and the apparatus becomes a real battery of twenty cells; it is whilst connected in this manner that the battery is discharged; the power at the beginning of the discharge is equal to thirty Bunsen elements of very large surface.

As the discharge proceeds, the tension falls, as we have explained when speaking of the single secondary element. If one minute has been the time occupied in charging the secondary battery,

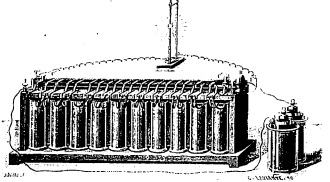

FIG. 4.—*Secondary Battery of twenty elements capable of being charged with two Bunsen elements when arranged for quantity, and producing light when being discharged with intensity connections.*

in quantity, from the two Bunsen elements, it cannot be expected that the discharge, in intensity, will produce the effect of thirty Bunsen elements of the same size during more than four seconds, for the apparatus does not produce electricity, and can only transform that which is imparted to it. M. Planté has made exact experiments upon this point, and has found that in the transformation about one-tenth part is lost, or, in other terms, that the apparatus gives back nine-tenths of what has been expended.

It is easily perceived that the secondary battery can only produce effects of short duration, but in a very great number of cases such effects are all that is required.

If, for example, it is desired to explode simultaneously a large number of mines by means of fuses of fine wire, the object can be attained by joining all the fuses as branches out of a single wire, and discharging a secondary battery into all of them simultaneously. This plan is a very economical one; there is no doubt that it involves much less labour and cost to set up two Bunsen elements and charge the secondary battery than to charge the twenty or thirty Bunsen elements whose place is supplied; it being of course understood that the work is required from the battery during but a few seconds, and that the operation is repeated but four or five times in the course of the day. Moreover, the secondary battery can be easily carried about to the different workshops where the works extend over a considerable area, as during the construction of a long tunnel or the sinking of shafts for mines.

In small laboratories the expense of setting up a large Bunsen battery is an obstacle to the carrying out of certain experiments, either for demonstration to pupils or for the investigations and researches of the teacher. The greater number of these experiments become possible by the use of the Planté battery. If, finally, this apparatus is used in combination with a Gramme machine in steal of an ordinary battery, all handling of acids is got rid of as well as all other expense except the purchase of the apparatus, which will last an indefinite time.

We have the greatest confidence in the future of this combined employment of the secondary battery and the Gramme machine, and we shall show in conclusion how it furnishes a solution to the important problem of lighting ships with a view to the avoidance of collisions at sea.

It is not by any means necessary to exhibit at the top of the mainmast a permanent electric light; it will be enough to secure a vessel from collision if it gives warning of its presence around the horizon by a signal of two seconds duration shown once a

THE TELEGRAPHIC JOURNAL.

Vol. II.—No. 42.

ON THE EFFECTS OF POLARISATION WHICH RESULT FROM THE PASSAGE OF CURRENTS THROUGH BAD CONDUCTING MATERIALS.*

By the COUNT DU MONCEL.

In my preceding articles on the electric conductivity of figurative bodies I showed that these substances are chiefly conductors by reason of the moisture they absorb. A similar effect is found in most mineralia, and certain of them even possess this property so highly that very sensitive hygrometers may be formed of them. Calcareous stones of a fine grain, like the stone of Caen, are of this description; and the moisture pervading them in consequence of their contact with atmospheric air suffices to furnish, with zinc and copper electrodes fastened to the extremity of a small prism 10 c.m. in length, currents—varying with the moisture of the air—capable of affecting a sensitive galvanometer. Hard, unexpalishable stones, also, have a conductivity varying with atmospheric moisture, but to a less degree, whilst a moderately strong and prolonged heat will diminish it considerably. Like hard woods, these descriptions of stones, having slowly parted with their moisture, as slowly take it up again. This gives most curious effects. With regard to this I will give at a later date some details, and I will speak, at the same time, figures to represent the conductivities of different kinds of stones. At present I wish only to refer to certain effects of polarisation that presented themselves on studying the conductivities of these substances, and which are so far beyond known effects that grave errors might be committed if we contented ourselves with a superficial glimpse of them. The following experiment, wherein these effects showed themselves as great as to make it impossible to be overlooked, induced me to investigate them:—

Desiring to measure the conductivity of an excellently irregular piece of yellow silex, I enveloped the two extremities in very thin platinum plates, so shaped as to fit the irregularities of the ends; and to attach the plates more firmly to the stone, I used for the one end a small iron vice, for the other a copper nipper. On closing the circuit, the current from my bichromate of potash battery, of six elements, gave a deflection of 30°. and, leaving the whole concern to itself, I was surprised —at the end of ten minutes—to read a deflection of 45° instead of having to register a great diminution as results of polarisation,—a diminution which with substances are, in the space of ten minutes, often become equal to half the first strength; and yet, by breaking the circuit and rejoining up the electrodes to the galvanometer, I was able to record a polarising current of 12°, which required ten minutes to completely disappear. By reversing the polarity of the electrodes—that is to say, by changing the electrodes' connexions with the battery—I obtained at first a deflection of 55°, which became reduced at the end of ten minutes to 28°, and yet the polarising current was only 9°.

* Communicated by the Author.

A fresh inversion of the electrodes' polarities gave a deflection of 38°; but this did not rise to 42° at the end of the ten minutes, until it had fallen to 35° in the first moments of the experiment; the polarising current was 10°.

These experiments, repeated a great many times at different periods, and always with the same results, caused me to examine attentively the arrangement of the experiment. I ascertained that the increase in current strength by prolonging the closure of the circuit only took place when the iron vice was in connexion with the battery's negative pole. On the other hand, on taking off my electrodes, I no sooner had that which corresponded to the iron vice was slightly pierced by one of the stone's rough edges. Therefore the phenomenon was easily explained, for it was in consequence of a copper and iron local couple created in the heart of the stone, which—by interfering with the effects produced by the battery and by the polarising currents—modified them, in effect or reverse, according to the direction of the battery current through the stone.

In the case in which the electrods in contact with the iron vice is in communication with the positive pole, only ordinary effects are produced. The local and battery currents flow in the same direction through the stone, like currents from two batteries joined in series placed in two different points of a circuit, and the strength of the battery current is naturally augmented by that from the local current. Hence we have the greatest observed deflection—viz., 55°—as compared with that produced under similar circumstances with the current reversed; and, since the effects of polarisation are in ordinary currents, the diminution of deflection takes place in a continuous manner, more rapidly than in liquids, on account of the slow dispersion of the polarising gases. Nevertheless, as at the moment of breakage of the battery current and of metallic tension of the two electrodes, the polarising current becomes inverse in direction to that of the battery, whilst the local current remains under the same conditions, the polarising current which is collected is only a differential one, and might even be overcome by the polarising current, if the local currents were sufficiently energetic.

In the instance when the established electrode that in connexion with the iron vice is in communication with the negative pole of the battery, *that electrode receives the deposit of hydrogen* which provokes polarisation; and, *as the oxidation of this gas substitutes itself for that of the electrode itself which is more or less enchroped*, as the case may be, *different effects may result therefrom, according to the relative energy of the electromotive forces of the local and polarising currents.* In the case when the local current is the most energetic, the effect of the cancelling of the metallic oxidation ought to result in *an increased force of the battery current, by destroying more and more the contrary force which had previously weakened it.* When the two electromotive forces are able to counterbalance each other, the strength of the current may remain sensibly the same, at least during a certain time. Lastly, when the polarising current's electromotive force overpowers it, the current should continue to become weak, but in a much less degree than when the battery and local currents are together. This effect I have been able to obtain in other experiments, quite easily, by employing a condensing current less powerful, that is, by diminishing the electromotive force of the battery.

THE TELEGRAPHIC JOURNAL.

The value of T in) independent of the way in which electricity escapes from the conductors; it is easy to see, therefore, that this value remains the same when two equal quantities of contrary electricities recombine themselves. Let us suppose, in effect, that two quantities of electricity $+a$ and $-a$ recombine upon a value M, in order to form neutral electricity; let V be the potential function of this point. Let us suppose, that, at the point M, the $+a$ electricity to be repulsed by a force $= a\,\frac{dV}{ds}$; the portion of the work T necessary to extend $+a$ to infinity, starting from the point M, is V a. The quantity $-a$, on the contrary, placed at the point M, is attracted, the attractive force has the same value as that of the repulsive force, and when $-a$ is extended from M to infinity, the corresponding work is equal to the preceding, and of contrary signs. The value of T remains consequently the same, whether the two electricities are extended to infinity, or whether their recomposition takes place at any known point; it is necessarily the same if the recomposition is produced upon a conductor.

This is the case presented, for example, in the discharge of the Leyden jar. Let us consider a spherical bottle; let us call r the radius of the sphere which forms the interior armature, r the thickness of the glass. If we designate by q the charge of the interior armature at a given instant, by dq the quantity of electricity repulsed from the interior armature upon the exterior armature, when these two armatures are connected by a conductor, the work effected in the repulsion of the quantity of electricity dq is—

$$\int_{r}^{r+e} \frac{q\,dq}{dr^2}\,dr = q\,dq\left(\frac{1}{r} - \frac{1}{r+e}\right) = q\,dq.$$

The work of repulsion which corresponds to the quantity of electricity q, primarily contained on the interior armature is—

$$R = \left(\frac{1}{r} - \frac{1}{r+e}\right)\int_{q}^{0} q\,dq = \frac{1}{r}\left(\frac{r}{r+e}\right)q^2.$$

The factor contained in the parenthesis represents the potential function of the interior armature; we find then, in the particular case of the Leyden jar, the expression for the potential of the electricity.

We may deduce from what precedes the demonstration of a theorem established by Gauss in the case of a system conducting and submitted to generalised by M. Liouville for a system of conductors. When conductors endowed respectively equal quantities of the two fluids, all those conductors are in a mutual condition, in effect, in this case, the potential is nil; consequently the exterior discharge of the system of conductors cannot give place to work.

ON GALVANIC POLARISATION IN GASLESS LIQUIDS.*

By Professor HELMHOLTZ.

It is known that when a Daniell's element is connected with a water-decomposing cell by platinum electrodes, a current flows, which soon, however, decreases and becomes very weak, but does not quite cease, even after a long time. We may call current this the *polarising* current. If the decomposition cell is then separated from the Daniell, and its platinum electrodes are connected with a voltameter, we have another current, the *depolarising*, which is opposite in direction to the former, and, from being at first strong, soon decreases, generally, till it becomes imperceptible.

This simple experiment was my starting-point. The difficulty presented itself—Why has the polarising current an apparently unlimited duration? For in a circuit of the kind described, unless some other changes occur, the electrolytic conduction in liquids (according to Faraday's law) cannot take place without a violation of the law of conservation of force. If, that is, no other equivalents of potential energy be consumed, then the mechanical equivalent of the heat produced in the circuit must be equal to the work-equivalent of the chemical forces brought into action in electrolysis and consumed. The latter, however, is *negative* if the decomposition take place according to the law of electrolytic equivalents, and consequently cannot be equal to a *positive* heat-work produced by the current. Decomposition of water, therefore, if Faraday's law is exclusively applicable here, cannot be continuously maintained by a Daniell, even in the smallest degree. An example of the liberation of the gases forming water comes after a time in the above experiment.

But it is not to be thought that by diffusion, or some like process, the molecules of hydrogen and oxygen, forced against the plates by the polarisation of them, become free again, returning to an electric state from the plates. Such a phenomena would ever more give a work-equal to decomposition of water for which no equivalent of force would be found in the Daniell. The electrical attraction of the two elements, strong enough to overcome chemical affinity, could only be overcome by a force of equal or greater equivalent of work, so as to set the attracted particles at liberty in the liquid.

If, now, the electromotive force of the Daniell, in our present case, produces no visible decomposition of water, it produces polarisation of the electrodes, and this is itself a work-equivalent. For the polarised plates are, afterwards, when separated from the Daniell, capable of giving a current which bears a considering wire, and produces other effects of current.

The state of polarisation is to be regarded as a new state of equilibrium to which the decomposition-cell tends, under electrisation of the electrodes; and if the electricity accumulated in the electrodes can discharge itself, the cell tends to return to the state of electro-neutral equilibrium. But since, for the production of an altered equilibrium in a finite system of bodies like the decomposition-cell, an only finite amount of work is necessary, the production of polarisation must only give a current of finite duration, or one whose intensity approaches zero asymptotically; and the polarising current can make only so much electricity flow in the one direction as the depolarising in the opposite direction.

In so far as this is the case,—and my experiments show that with gaseless liquids and gaseless electrodes we may come very near such a state,—the decomposition-cell acts like a condenser of very

ELECTROLYTIC POLARISATION.—Professor W. E. Ayrton and John Perry, from experiments carried on by sending a current from one or more Daniell cells through a voltameter and measuring its strength after a certain number of minutes, then suddenly reversing and observing the current strength a fixed time after, find that when the cathode is of copper wire, the anode being a copper plate, there is a quick falling off in the first current and a slow falling off in the reverse one; with a platinum wire cathode opposed to a platinum plate anode the reverse effect takes place; but with a platinum wire anode the same effect takes place. Messrs. Ayrton and Perry explain these facts by pointing out that since the surface of the wire in the voltameter is extremely small compared with that of the plate, the gases deposited on the wire will have more effect than those deposited on the plate in the polarization of the voltameter; and also that oxygen deposited on copper will, on account of its forming an oxide, be less operative in producing a reverse current than hydrogen; while on the other hand on account of the great absorption of hydrogen by platinum and of the difficulty of forming an oxide of platinum, it will be deposited oxygen that will produce the chief polarisation in the platinum voltameter.

POLARISATION.

So much interest is shown by our correspondents in the difficult subject of polarisation that we have determined to collate into a series of papers the opinions and deductions of foreign scientists. Reference will be made, *en resumé*, to the labours of our countrymen, and these remarks will include the description of several original experimental results with which we have been favoured. The chief labourer in this field recently is the Count du Monsel, and we will commence the series with a translation of the table and accompanying article from the *Comptes Rendus*, on the effects produced by electric currents on mercury immersed in different solutions.

"In my last two communications on the action produced by currents upon mercury immersed in solutions of sea-salt, of cyanide of potassium, &c., I have principally attributed the origin of the secondary current, which is produced at the same time as the current of polarisation, to a resultant action of the combination of the two gases disengaged at the two electrodes; but some later experiments have shown me, as I have indicated in *Les Mondes* 12th April, that the effect is more complex, and is related to the action of the metals entering the saline solutions and the amalgams of mercury under electric influence. Having removed the globule of mercury from the electrolytic solution, and washed it with distilled water, the water became alkaline. After this experiment there was no longer a doubt that an amalgam of sodium and potassium is formed in the same manner as the ammonium-amalgam with a solution of sal-ammoniac. The effects which I have described are thus capable of very simple explanation.

"The work I have since undertaken on this question has shown me that, conformably to the observations of M. Planté, the mercury employed as electrode in an electrolytic may increase the evolution of secondary currents, more or less powerful, according to the energy of the chemical effects developed by the mercurial electrode, whatever may be its polarity.

"When mercury constitutes the negative electrode, these secondary currents accrue most often from the amalgams formed, and the energy of these currents depends upon the degree of oxidability of the metal alloyed with the mercury, the degree of concentration of the solution, the greater or less facility with which these metals alloy with the mercury, and, finally, upon the stability of their saline combination. The extension of action of these currents, on the other hand, appears to be in relation with the time of electrolysation, and to depend upon circumstances which permit a larger quantity of the metal to amalgamate with the mercury. Generally, the first action of these secondary currents, which is similar to that of the polarisation current from the reaction of gaseous elements, remains nearly the same for from five to fifteen minutes, but the differences increase after five to ten minutes' interruption of the polarising current. Sometimes, also, there is formed upon the negative electrodes, when these are insoluble, particular deposits which, without being a metal, are susceptible of furnishing an energetic chemical reaction; this occurs with the solution of sal-ammoniac when the negative electrode consists of a plate of platinum: there is then produced a secondary current, most transient it is true, which attains at the first moment an intensity of 40°, whilst with ammonium amalgam the intensity is only 56 to 60. It may be remarked that the platinum plate is covered with a brown deposit, which is strongly adherent.

"One important point is, that a very small proportion of a salt is capable of furnishing a very energetic secondary current. Also, that a solution of pure sulphate of binoxide of mercury does not give rise to an appreciable secondary current; but carbonate of soda or sulphate of zinc, however, affords a most energetic current. It is from this cause that sulphate of mercury batteries, when they are new, polarise but little, and whether there has been some time in use become very inconstant, because the mercury reduced in contact with the carbon is surrounded by a solution more or less impregnated with sulphate of zinc, or with other salts which always exist in the commercial sulphate of mercury. It is for this reason that I have advised the construction, for this kind of battery, of porous cups with a double bottom pierced with holes, in order to isolate the carbon from the mercury and from the liquid charged with sulphate of zinc."

When the mercury constitutes the positive electrode there are also produced very energetic secondary currents, which more often accrue from oxidation of the mercury, and the reduction of the salts by the hydrogen condensed on the negative electrode. These currents are much less permanent than those which are set up by the negative electrodes. The most important occur with solutions of sulphate of soda, sulphate of zinc, sulphate of iron, and sal-ammoniac. Sometimes the currents are more energetic, for the same solution, than when they are obtained by a negative mercurial electrode. At other times the contrary obtains; and in order to give an idea of the said results, I have composed the accompanying table, which indicates not only the intensity of the currents after different periods of interruption* of the polarising current, but also the initial current due to the action of the solution on the mercury. These intensities were given upon a zinc-platinumeter of 24 turns, with a resistance equal to 12 kilom. of telegraph wire (4 m.m. diam.). The primary current was derived from a battery of eight Chaloux elements, charged some time before, and the figures are the mean of a certain number of experiments, made at different times. The experiments were difficult to perform, on account of the inconstancy of the currents.

Time of Expiration of the Polarisation Current.—Prof. J. Bernstein.—Suppose a constant current sent through a decomposition cell, and the electromotive force, of a given moment, to disappear, it is required to find the time at which the polarisation current diminishes in the same manner to zero. The author describes a number of experiments bearing on this. It is shown, *inter alia*, that the curve of polarisation currents is only in the first moments an approximately logarithmic one; in course of time it departs more and more therefrom, while it sinks more slowly to the line of abscissæ. This is explained partly by the behaviour of the gases deposited on the electrodes, smaller quantities of gas collecting more tenaciously to the metallic surface. The mode of solution of hydrogen by many metals, and the change of surface of the hydrogen electrode, also influence the phenomenon. From another series of experiments, it was proved that the electromotive force of polarisation in a closed circuit, resistance and surface of electrodes remaining the same sinks the more slowly the greater its initial value; with increase of this, the velocity of disappearance, up to the maximum of polarisation, approximates to a minimum, and with decrease it approximates to a maximum.

curves, which, garland fall poles alaove and quantity of material, as curves were often close

Once the arrangement remained at rest in the any further action of t

The arrangement also continued after the current ceased to act. The crystallites were always directed so that their longer axes lay in the direction of the curves.

The same behaviour was exhibited by various powders suspended in water, viz., copper-oxide, chrome-oxide, sulphide of iron, cinnabar, glass powder, fluoride of calcium, black *Indian* ink, carmine, coal, bubbles of oxygen and hydrogen, hypochlorite (previously boiled, to prevent boiling together), copper, platinum, zinc, and brass. The conductors of electricity among these substances presented a more complex phenomenon, for the metallic particles, with whirling motions, changed their places extremely quick, and at the same time little gas bubbles rose from their projections in the liquid. This development of gas, which was only observed from powders of metal, appears to arise from a decomposition of the water, and not from adherent air particles, etc., such an adherence would also have been observed in non-conducting powders. This gas-development makes the rotary movements of the metallic particles intelligible. Both phenomena are absent when the electricity acts only a short time; in this case the curves of metallic particles take the same form as those of non-conductors.

Thus the good conductors differ from the other bodies examined, inasmuch as they very soon change the position required through the alternating currents, in consequence of development of gas, due to a dielectric charge of the particles, and for the same reason a state of rest of the system, such as in the case of non-conductors and semi-conductors, does not occur.

To elucidate the cause of the phenomenon a series of modifications were introduced into the experiment. First, the conductive resistance of the distilled water in which the particles were suspended was diminished with ordinary salt or some sulphuric acid; the effect of this was that the phenomena of direction and arrangement were absent.

A constant battery current being allowed to act on the particles suspended in water, instead of the alternating currents of the induction apparatus, the long-known phenomenon of transference could be observed; the particles wandered (with a certain strength of current) towards the positive pole. A double movement of the particles was frequently perceptible. When the water was rendered conducting the transference phenomenon ceased.

When the constant current was, by means of a tooth wheel or other arrangement, frequently interrupted, so that intermittent battery currents, going in the same direction, acted on the suspended particles, these latter moved towards the positive pole, just as in the case of the uninterrupted battery current. The movement was a continual, not a jerking one when the number of interruptions was not too small. With exalted conductivity of the water, the phenomenon did not occur. It must, however, be remarked that the intensity of the currents available was not sufficient to carry forward

ELECTRIFICATION OF PARTICLES FLOATING IN WATER.

If coarsely pulverised Iron nuts be shaken with ether, there appears a white powder which shows a distinctly crystalline structure under the microscope. The so-called crystalloid forms obtained thus have been subjected by M. Wegt to the action of electric currents under the microscope. For this purpose two triangular pieces of tin-foil were fixed in a glass plate with opposite points about two millimetres apart. Between them was put a drop of distilled water, in which the crystalloids were suspended. When the alternating currents of a sliding induction apparatus were sent through the crystalloids, which before were quite irregularly distributed in the water, arranged themselves in a perfectly regular manner under the microscope into a position parallel to the direction of the current. After several discharges nearly all the particles were brought into the parallel direction, with exception of the larger particles, which were hindered by friction on the glass. Further opening discharges on the directed particles drove them towards the positive pole. In one case, when copper powder and quartz powders floated in the water, the "reduction of the particles was at first produced quite as usual, but, on making further opening discharges, the copper particles wandered towards the positive pole, the quartz particles towards the negative. If to the opening discharges were made in close succession, the particles stood with their long axes in the direction of the current, arranged in curves, as in the first experiments. Each further opening discharge approximated the particles to the positive pole. On addition of common salt or sulphuric acid all these phenomena disappeared.

Lastly, when alternating currents from a constant battery were caused to act on glass powder, coal, Indian ink, or carmine, distributed in water, each particle kept the same place which it had before the action of the current, during its action, and the particles were arranged in the usual regular curves their longer axes lay in the direction of the curves. These experiments prove that the action of the induction alternately with the and the alternating currents of a constant battery are the same; but they especially show that the state of rest of the curve system may be regarded as a function of the alternating currents.

The phenomena here described, of direction and still state of the particles, M. Wegt explains by the supposition, according to Faraday's view, that each particle reached by the current (conductor, half-conductor, non-conductor) becomes dipolarly electrical thereby. The separated electricities accumulate in each particle with predominant longitudinal direction at the two poles, and in consequence of the alternation of the two tinfoil poles, the charged particles must take direction. Each individual particle must attract the other, and so there arises a chain of particles whose oppositely charged poles are turned to each other.

"All this," says M. Wegt, "holds good for the case in which a single current impulse of short duration has come upon the particles suspended in water. If now the direction of the current impulse is altered every instant, the attraction and direction of the particles produced by the first current impulse will not experience any change through the second current impulse, which is oppositely directed to the first; this merely reverses the signs of the poles. And the particles do not any further change their place under influence of the second impulse, since they are already, through the first current impulse, in the place to which the attracting or repelling forces of the two neighbouring poles of opposite sign have brought them. All subsequent current impulses act in like manner."

The curves in which the particles arrange themselves, which, garland fall poles alaove and quantity of material, as curves were often close

Once the arrangement remained at rest in the any further action of t

The arrangement also continued after the current ceased to act. The crystallites were always directed so that their longer axes lay in the direction of the curves.

The same behaviour was exhibited by various powders suspended in water, viz., copper-oxide, chrome-oxide, sulphide of iron, cinnabar, glass powder, fluoride of calcium, black *Indian* ink, carmine, coal, bubbles of oxygen and hydrogen, hypochlorite (previously boiled, to prevent boiling together), copper, platinum, zinc, and brass. The conductors of electricity among these substances presented a more complex phenomenon, for the metallic particles, with whirling motions, changed their places extremely quick, and at the same time little gas bubbles rose from their projections in the liquid. This development of gas, which was only observed from powders of metal, appears to arise from a decomposition of the water, and not from adherent air particles, etc., such an adherence would also have been observed in non-conducting powders. This gas-development makes the rotary movements of the metallic particles intelligible. Both phenomena are absent when the electricity acts only a short time; in this case the curves of metallic particles take the same form as those of non-conductors.

Thus the good conductors differ from the other bodies examined, inasmuch as they very soon change the position required through the alternating currents, in consequence of development of gas, due to a dielectric charge of the particles, and for the same reason a state of rest of the system, such as in the case of non-conductors and semi-conductors, does not occur.

To elucidate the cause of the phenomenon a series of modifications were introduced into the experiment. On Rotatory Magnetic Polarization. — Henry Becquerel.—It has been remarked that bodies endowed with strong rotation generally possess a great magnetic rotatory power; but the exceptions seem to this rule hinder the full acceptance of these two physical properties. Thinking that if bodies were endowed with rotatory refracting, the influence of refraction might become convincing, and that it would be possible, under these conditions, to display a relation between refraction and magnetic rotation, a very powerful electro-magnet was made use of, through whose armatures was pierced a cylindrical hole following the line of the poles. The measure of the rotations was effected by means of one of Jullet's penumbra polariscopes. The sources of light were the mono-chromatic flames of sodium, of thallium, and the flame of lithium seen through red glass to eliminate the orange light. Several experiments were made, and tabulated in two tables. In one of them the substances chiefly comprised compounds of chlorine, phosphorus, sulphur, and carbon, and they present a regular increase of rotation for the same length of wave, in proportion as the index of refraction increases. The second table does not show the same feature of regularity; and this may be attributed either to effects of lamellar polarisation, as in the diamond and garnet, to the presence of magnetic bodies, or to unknown causes. May we not possibly account for these effects by assuming that the rotation of the plane of polarisation to be due to an action of magnetism upon the inter-molecular ether, and that at the same time the molecules of the body influenced are magnetically polarised, so as to present poles of a contrary name to those of the magnet. These molecules will then be as many small magnets inverse to the magnet influencing them, and acting at very small distances upon the medium which transmits the luminous vibrations. The intensity of this action is eminently variable with different bodies; it may depend upon their specific magnetism, and upon the reciprocal distance of the molecules. It is thus possible to conceive that the true action of these molecules may considerably lessen the action of the magnet; and even if the body is very magnetic, and under suitable conditions, this molecular action may become preponderant, producing a negative rotation as is observed with certain kinds of magnetic metals. *En resumé*, the experiments demonstrate that in bodies feebly magnetic and very refracting, which have not hitherto been studied, the increase of the magnetic rotatory power follows as a rule the increase in the index of refraction.

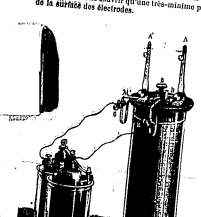
20. Les electrodes sans polarisation, par Overbeck. (Ann. de Poggendorff, vol. CLIV, page 445).

Du Bois-Reymond avait trouvé que des plaques de zinc amalgamées dans des solutions de sels de zinc ne se polarisent pas sous l'influence du passage du courant. D'après M. Oberveck, cette découverte ne serait exacte qu'autant qu'il s'agit de courants faibles. Si l'on emploie des courants d'une intensité un peu forte, les effets de la polarisation, par suite de la décomposition de l'eau, se produisent sur ces électrodes comme sur des électrodes formés d'un autre métal quelconque.

[32.IX.] — **Plante's Secondary Battery.** — I. The capacity of the cells usually used for secondary batteries is about 11 pint; the limiting pressures are 0·07 to 2·3, diameter. 2. If you want a "simple form" employing the electric light by the "simple arrangement" of the size of the primary battery with platinum, for each cell, do the next following cells. Connect the free wire of your primary battery with the first plate of lead of your first cell of your secondary battery, and the free carbon of your primary with the last lead of the last cell of your secondary battery. Now suppose you work with the four plates of which you have two in each cell, the one in each cell with the letter *L*, the other with the letter *P*. Then connect in each plate marked *L* with the plate marked *P* in the following cell. This is coupling for electro-motive force. For obtaining heating effects join all the plates marked *L* to one primary wire, connected with the carbon of your primary battery and all the plates marked *P* to the platinum wire. The same. 3. Six of these cells charged for one hour or two Bunsen cells charged for thirty minutes equal to three of Grove's or thirty Bunsen cells.—WILDERMANN

plus volumineux; M. G. Planté en a conclu qu'il y avait lieu de les rechercher et de les mettre à profit pour accroître la force électro-dynamique. Cet effet qu'il obtint réellement en 1860 au premier étonnant secondaire de grande intensité, formé de deux longues et larges lames de plomb enroulées en spirale, séparées l'une de l'autre par une toile grossière et plongées dans du bois plein d'eau acidulée au 1/10 par l'acide sulfurique. — Il lui suffit de multiplier plusieurs de ces couples pour former une batterie secondaire de grande surface. La seule modification qu'il apporta à cette disposition primitive fut de substituer à la toile des lames de caoutchouc présentant l'avantage de ne pas s'altérer dans l'eau acidulée, et de ne couvrir qu'une très-minime partie de la surface des électrodes.



Pile secondaire en train de se charger.

Étudiant ensuite très-savamment les actions chimiques produites dans ses couples secondaires à lames de plomb, l'auteur expose les conditions suivant lesquelles il doit être procédé à leur *formation ou préparation* électro-chimique de manière à en obtenir le maximum de résistance et le plus grande intensité de charge.

Le couple secondaire ayant été rempli à l'avance d'eau acidulée au 1/10 par de l'acide sulfurique pur, on le fait traverser, le premier jour et pendant une heure, par un fort courant alternativement dans l'un et l'autre sens, et on huit fois, dix minutes de charge, dix minutes sens inverse de courant de deux éléments Bunsen. On déchargea le couple secondaire entre chaque changement de sens, et on recommence, sans pause autre effet, que la durée de la décharge va sans cesse en croissant.

La disposition faite à tout le temps pendant lequel le couple reste soumis dans le même sens à l'action du courant jusqu'à ce qu'il donne à l'heure et 1 heure on le laisse reposer, ensuite chargé dans un sens déterminé pendant une heure. Le lendemain, on les recharge deux heures en sens inverse, puis deux heures dans le premier sens et ainsi de suite. On constate les progrès de la formation à l'aide du volta. On constate les progrès de la formation à l'aide du voltamètre.

Après un certain nombre de charges et décharges successives, on arrive à un maximum de résistance et de force électro-motrice. Mais il arrive bientôt une limite au delà de laquelle cette durée n'augmente plus sensiblement, surtout lorsque la pile primaire n'était pas puissante, c'est difficile peu à peu par de actions successives et n'a plus une intensité suffisante pour que l'électrolyse pénètre plus profondément à l'intérieur des lames.

On laisse alors le couple secondaire au repos, pendant huit jours, et on le recharge pendant plusieurs heures, sens faire, le même jour, de nouveaux changements de sens, puis, au porte peu à peu l'intervalle de repos à quinze jours, un mois, deux mois, etc., et la durée de la décharge va sans cesse en augmentant. Elle n'a d'autre limite que l'épaisseur même des lames de plomb. La lame positive, en effet, finit par être transformée presque entièrement, avec le temps, en peroxyde de plomb à texture rigide. La lame négative se trouve peu à peu formée, jusqu'à une certaine profondeur au-dessous de la surface, de plomb réduit, spongieux et cristallin.

Il n'est pas toutefois nécessaire de pousser la préparation électro-chimique des couples secondaires jusqu'à cette transformation complète de la nature physique et chimique des lames; car les couples finissent alors par acquérir une plus grande résistance et exigent plus de temps pour être chargés.

Lorsque des couples secondaires donnent une force suffisamment puissante pour l'application qu'on veut en faire, il n'y a plus lieu de changer le sens du courant primaire, chaque fois qu'on veut les mettre en circuit primaire, plomb secondaire sur la lame positive avait trop longue à produire, et l'on n'abandonnait aucun effet de couple avant plusieurs heures. On arrive dans un sens déduit dans qu'ils sont suffisamment formés.

Rien n'empêche de multiplier indéfiniment le nombre des piles Planté, comme on le voit par la photographie du laboratoire de l'inventeur.

Les couples secondaires acquièrent, par l'opération de la *formation*, une propriété précieuse : celle de conserver une grande partie de leur charge pendant un temps assez long. Après l'action du courant primaire, ils peuvent rougir un fil de platine d'un demi-millimètre de diamètre, pendant quelques minutes, deux ou trois semaines après avoir été chargé.

—

Les applications des courants secondaires à la galvanoconstique et à la thérapeutique sont très-fréquentes aujourd'hui, et tendent à se généraliser par l'emploi d'appareils très-habilement construits à cet effet, et pouvant être facilement chargés pour fournir, sans aucune manipulation auprès d'un malade, la chaleur nécessaire à l'opération. La puissance d'électricité emmagasinée dans un couple secondaire suffit même pour exécuter plusieurs opérations successivement sans avoir à le recharger.

Il serait impossible de donner une nomenclature complète des usages innombrables auxquels est appareil si intéressant se prête.

Nous devons cependant faire remarquer qu'il est admirablement disposé pour l'éclairage des cavités obscures du corps humain et des cavités obscures en général à l'aide des pyroscopes de M. Trouvé, l'habile constructeur, que tant de dispositions ingénieuses ont signalé déjà aux savants.

Parmi les applications qu'on peut faire des couples et des batteries secondaires, l'une de celles auxquelles ces appareils se prêtent le plus naturellement est l'*inflammation des mines*, car elle n'exige qu'un effet calorifique de courte durée, répété à certains intervalles.

Nous signalerons encore le *lebiquet de Saturne*, petit instrument si commode pour obtenir facilement du feu dans les laboratoires et pour les usages domestiques.

Les batteries secondaires peuvent produire des effets d'une énergie prodigieuse dans la manœuvre des *freins électriques* sur les chemins de fer; elles donnent à la guerre des effets lumineux instantanés d'une force inouïe.

Du moment qu'on n'a pas besoin d'une action longuement continuée, on peut dire que M. Planté a trouvé moyen de mettre véritablement la foudre en bouteille.

STORING ELECTRICITY.

[17196.] Crard, Jean-Jacques-Alfred-Napoléon, Count, and Gaulard, Lucien, Engineer, both of Paris. [Provisional protection only.] [Dated 7th October, 1882.]

"If, it is said, we could store up electricity, as we can water or steam, we should have a motive power which would be much more economical than any other." (17195, p. 129) that has been referred to as the "ideal case. The fact is, "not realising the importance of the idea from any fear that we may ever discover a means of doing so. The importance, and that it is nothing but what I, in common with every scientific electrician, have been constantly dealing with this many a year. If [illegible] I have put forward to "day not far distant when it will be possible to purchase of "electricity sufficient to work a number of electric lights, when exhausted, they will return to the central station, "to be there what many people do not know every in the distance for what lies under their noses, "and every [illegible] battery. As I pointed out my former paper, the "storage of electricity" is nothing but a common gravity form of "[illegible]" the only question about it is one as to the relative charging and convenience of charging it at [illegible] and the [illegible] of copper and zinc, or pondering these relationships in the cell itself by means of electrolysis. I think it will be possible that the conditions named might be modified, but to settle it would require experiment and time, which I do not feel inclined to undertake; but I can say this at once: to store the work from a 1-horse power engine in an 8-volume gross of work, requires how the effort may be reduced to a minimum of trouble or expense.

"But the fact of the principle of least action being mathematically deduced from the principles of motion would seem to prove that there is, in reality, no choice in the matter, and that the most economical system is such as that of the least distance between two points on a sphere being that which is traced by the great circle joining them."

After treating this geometrically and dynamically, he urges that "the dynamical minimum stands on the same footing as the geometrical . . . . I think we ought to recognise the fact that there is unity in the order of nature, that the mind must be at last satisfied with nothing short of the great Arithmetic, and in reality be the result of geometrical and other necessity, inherent in the conditions of space, or time, or matter."

Scientific.

ELECTRICAL RESISTANCE.

[17196.] Langdon, J. Brown, 23, Bedford-street, Strand, London. [Dated 7th October, 1882.]

This is a thoughtful and intelligent title where there is much to approve and admire; but, as it is not all gold that glitters, one might perhaps administer a gentle rebuke to that fatally characteristic feature of modern science which leads to research and mystery, ultimate results which, in the main, are not the result of facts are often [illegible] distorted in the scholastic methods of an illegitimate explanation. Let us cite two cases in the law of gravitation, and that of gaseous tension or pressure, taking Clerk-Maxwell's lucid definition of the latter.

"The distinguishing property of gases is their power of indefinite expansion. This has sometimes been explained by supposing that the molecules of gases are in rapid motion, and that they act at first sight, but on it is not all gold that glitters, one might perhaps administer a gentle rebuke to that fatally characteristic feature of modern science which leads to research and mystery, ultimate results which, in the main, are not the result of facts are often [illegible] distorted in the scholastic methods of an illegitimate explanation. Let us cite two cases in the law of gravitation, and that of gaseous tension or pressure, taking Clerk-Maxwell's lucid definition of the latter.

des lignes alternativement blanches et noires tournant avec une vitesse modérée, de manière qu'on y voie courir du papillotage; si, pendant qu'on le regarde, on se comprime graduellement les yeux, le papillotage s'efface et le disque se montre d'un gris uniforme, qui n'a nombril pas à yeux.

« M. Exner paraît faire dépendre le phénomène de ce principe, que l'action de la lumière épuise continuellement une substance photochimique nécessaire à la fonction visuelle, substance continuellement restituée aussi par un afflux dû à la circulation. Dans ses idées, en effet, pendant la compression des yeux, l'afflux libre de la substance visuelle tendait à ramener la rétine à son état normal pendant le passage de chaque secteur noir, et ainsi amoindrissait rapidement la persistance de l'impression incomplète engendrée par le passage du secteur blanc précédent; mais la compression diminuant l'afflux dont il s'agit et, amoindrissant ainsi la cause qui ramène la rétine à son état normal, l'impression persistante du secteur blanc décroît d'une quantité trop petite pour que l'œil puisse s'en apercevoir, et, par suite, la teinte grise lui semble uniforme. »

En réfléchissant à cette expérience, je me suis dit que si la compression des yeux amoindrit la réaction de la rétine, cette réaction doit perdre de son influence sur la largeur de la bande d'impression propagée, et qu'alors conséquemment l'irradiation doit s'étendre beaucoup plus loin. Comme M. Exner signale le danger de se comprimer ainsi les yeux, je n'ai pas osé soumettre à l'expérience les personnes qui observent pour moi; mais je trouve, dans deux Notes de Brewster[1], des faits qui apportent une nouvelle preuve en faveur de la propagation de l'impression, et peuvent, en outre, permettre de se passer de la compression volontaire des yeux.

Dans la première Note, il s'agit de l'affection passagère signalée par plusieurs auteurs et consistant en ce que le patient ne voit qu'une portion des objets. Brewster, chez qui cette affection s'est présentée plusieurs fois, a constaté que lorsque l'image de caractères d'impression ou d'autres petits traits sombres tombait sur la portion de la rétine ainsi affectée, ces petits objets disparaissaient complètement, sans que le fond sur lequel ils étaient tracés perdît de son éclat. Il en conclut que l'impression du fond était propagée par l'irradiation sur les images de ces mêmes petits objets, et il ajoute :

« ..... Les portions qui sont affectées dans ce cas, s'étendent irrégulièrement du *foramen centrale* au bord de la rétine, comme si elles étaient en relation avec la distribution des vaisseaux sanguins de cette membrane, et conséquemment il est probable que la paralysie des parties correspondantes de l'organe était produite par leur pression. Cette opinion aurait pu être considérée pendant longtemps comme une explication simplement rationnelle de l'hémiopie, s'il ne s'était présenté à moi un phénomène qui la met hors de doute. Pendant une attaque assez intense, j'allai accidentellement dans une chambre obscure, et je fus surpris d'observer que toutes les parties affectées de la rétine étaient légèrement lumineuses, effet qui est invariablement produit par une pression sur la membrane. »

La seconde Note commence ainsi :

« Dans un écrit sur l'hémiopie, ... j'ai mentionné

[1] *On Hemiopsy, or Half-Vision* (Edinburgh, or the Roy. Soc. of Edinburgh, t. XVII, 1865, volume publié en 1867, p. 15). *On a new property of the retina* (Ibid., ibid., 1868, p. 321).

le fait remarquable que les parties de la rétine qui sont insensibles aux impressions visuelles sont sensibles aux impressions lumineuses, la lumière étant due à une irradiation émanée par les parties adjacentes de la rétine. »

Et, plus loin, Brewster décrit une affection de même genre qu'il a constatée dans son œil droit, avec cette particularité qu'elle était permanente, et constituait ainsi une sorte d'amaurose locale, et il dit :

« Quand l'image d'un objet lumineux couvre en tout ou en partie cet endroit, elle est invisible; ..... l'œil est donc dans cette portion absolument insensible à la lumière qui le frappe tentant de l'extérieur; mais si je dirige l'œil vers le ciel, vers le plafond blanc d'une chambre ou vers toute surface blanche étendue, je ne vois pas, dans le champ de la vision, la moindre tache présentant le plus petit degré d'obscurité. Conséquemment la portion de la rétine insensible à la lumière qui tombe sur elle directement, c'est-à-dire de l'extérieur, est éclairée par l'irradiation des portions environnantes. »

Je n'ai pas besoin d'insister sur ces faits; il me semble impossible de les expliquer autrement que par une propagation de l'impression, et ils rendent bien probable comme je l'ai dit, qu'une compression artificielle, en même temps qu'elle diminuerait la sensibilité aux impressions directes, augmenterait au contraire la sensibilité aux impressions propagées. Il est vivement regrettable que l'expérience offre du danger, car si elle donnait le résultat que je prévois, c'est-à-dire un développement extraordinaire de l'irradiation, la théorie que j'ai soutenue serait absolument prouvée.

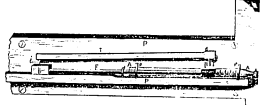
NEW GRADUATING APPARATUS.

This apparatus was designed to facilitate the accurate graduation of glass tubes—burettes used in volumetric analyses, technical assays, pharmaceutical work, etc.

The tube, A A', to be graduated is secured by brass clamps, *c c*, to the wooden frame, P. The piston, B, of brass, loosely packed with rubber, is rigidly connected by the brass rod, F, with the block, k. The smaller end of the glass tube, A', is tightly connected by a piece of rubber tubing with the glass tube, G, which joins, at right angles, the small upright graduated glass tube, E E. This tube is continued downward, and connected by a short piece of rubber tubing with the feathered delivery tube, D, a pinch cock serving to stop the tube at O. The upper part of the tube, from *e* to *e*, is graduated to contain one cubic centimeter of water, and this space is subdivided into tenths of a centimeter. Water from D is introduced into the tube through the small funnel. The hard-wood rod, T, has a fine steel point rigidly affixed at *s*, the other end being similarly fitted with a wedge-shaped blade, *p*.



In using the apparatus the tube to be graduated is uniformly coated with a thin film of white wax or collodion. A small quantity of water is then put into it, the piston adjusted so as to fit snugly but loosely, and the tube securely clamped in position, connection having been made with the tube, G, the pinch cock at O is opened, and the piston forced up to the end, A', of the tube, expelling the water (and air) through G and D. The pinch-cock is then closed and water (at 0° Fah., or 16° C.) let into the tube, E, from D, until it is filled to the mark, C, any excess being drawn off through D.

The block, k, is then grasped and slowly drawn back until the water in E E has fallen to *o*, the first mark on the scale. The steel point, *s*, on the rod, T, is then inserted in a fine hole, *nick*, or cut line on the upper side of the block, k, and held in position, while the blade, *p*, at the other end of the rod is brought down on the coated tube, and a fine line cut through the coating to the surface of the glass. The block, k, is again drawn back until the water in E E' falls to the next line on the scale, when the rod is brought into requisition, as before, and another mark made on the tube. These operations are repeated until the water in the tube, E E, falls to C', when it is again filled to C, from the reservoir, D, and so on, until the graduation of the tube, A A', is completed.

The lines are etched in by exposing the tube to gaseous hydrofluoric acid—evolved from a mixture of powdered fluor-spar and warm oil of vitriol contained in a suitable leaden dish—or by the use of liquid hydrofluoric acid. Wherever the film of wax or collodion has been cut so as to secure sufficiently etched in a few minutes.

The wax may be removed from the glass by washing with benzine, the collodion by hot water and a brush.

Tubes graduated in this way are much more accurate than those graduated by the usual methods, or where variations in internal diameter of the tube are not taken into consideration. The time required in the operation is reduced nearly one half over the older methods of volumetric graduation.

Statue of Marco Polo in Venice.

A statue of Marco Polo, discovered in Canton, has been received at his native city, Venice. It is life-size, made of wood, and gilt. According to a foreign contemporary, the Chinese artist, although the clock and hat are after the European fashion. His moustache and beard, which surround his face, are tinged dark blue, and while the Chinese artist has given him a peculiar form, the features in no way resemble those of a Mongolian type. Opposite the large, ray armchair upon which Marco Polo is seated is placed a porcelain bowl, intended to receive perfumes, with which he was honored in the same manner as in the processions at the feast, an Imperial [illegible] character.—

The Future Battery and the Electric Light.

Some experiments of considerable importance have lately been carried out by Mr. Keates, the Consulting Chemist to the Metropolitan Board of Works, in which a Faure accumulator has been employed in the production of the electric light. The lamps used on this occasion were respectively those of Maxim and Swan, one of each description being stretched at a time. Mr. Faure states that in those experiments 40 cells represent about half an available horse power for three hours. The Maxim light being placed in connection with the accumulator, 30 cells were found to give the light of 10 candles. With the same number of cells the Swan lamp gave the light of 22¼ candles, with 35 cells the lights became respectively 45·6 candles and 67·5. With 40 cells the Maxim light rose to 101 candles, and the Swan to 141. Thus far the Swan light gave the greatest amount of candle power. But with 45 cells the Maxim light rose to 229 candles, while the Swan only displayed 224. The capacity of the latter was evidently being overtaxed, for in about a minute the carbon loop broke. A power of 50 cells was then connected with the Maxim light, which then rose to 321 candles, but in about a minute the carbon loop shared the same fate as the Swan. The experiments are also interesting as showing the great increase of light obtained by a comparatively small increment of power. Thus, in the case of the Maxim lamp, taking 35 cells as the standard, an increase of one-sixth nearly trebled the light; an increase of two-sixths augmented the light more than six times; three-sixths increased it fourteen times, and four-sixths twenty-one times.

IMPROVEMENT IN TABLES.

The engraving represents a simple and inexpensive device for uniting the rails of tables and the legs with the rails in

LANGSTON'S IMPROVED TABLE.

L'EMMAGASINEMENT DE L'ÉLECTRICITÉ

Peut-on emmagasiner l'électricité, on, pour employer une expression plus figurative, peut-on mettre *l'électricité en bouteilles*, pour la dépenser ensuite d'une façon proportionnée aux besoins, jusqu'à complet épuisement du récipient qui la contient? C'est en nous plaçant à ce point de vue que nous voulons examiner rapidement quelques appareils qui nous permettent de répondre oui hardiment, à la condition de bien déterminer à l'avance dans quelle mesure cet emmagasinement peut s'effectuer.

Nous commencerons d'abord par la pile secondaire de M. Gaston Planté, car c'est celle qui a donné jusqu'ici les meilleurs résultats pratiques et fourni le plus grand nombre d'applications.

Pile secondaire de M. Gaston Planté. — Nous n'avons pas à décrire ici l'appareil, bien connu de nos lecteurs (voir *la Nature*, n° 56 du 27 juin 1874, p. 51), où à exposer sa théorie. Nous nous contenterons de reproduire (fig. 1) un élément du modèle primitif, dans lequel M. Planté a substitué depuis, à la boîte qui séparait les lames de plomb, deux lames élastiques de caoutchouc.

Quelle que soit la source électrique employée, la pile emmagasine le courant électrique et le restitue ensuite dans des conditions souvent tout à fait différentes de celles de l'emmagasinement.

Fig. 1. Pile secondaire Planté.

1° Nous avons représenté (figure 2) Planté ressuscitée expérience effectuée par MM. Gaston Planté et Niaudet en 1877, expérience qui est une des plus belles démonstrations de l'*unité des forces physiques* et de leurs transformations mutuelles. Une machine Gramme à aimant lamin transforme le travail mécanique en électricité, qui, emmagasinée dans une pile secondaire de Planté, s'y emmagasine. Si, après avoir chargé le couple, on arrête la machine, elle se remet en marche dans le même sens, sous l'action du courant produit par le couple secondaire, et transforme de nouveau le courant électrique en travail mécanique.

Fig. 2. Pile secondaire Planté chargée par une machine Gramme à aimant lamin.

Dans cette expérience, la machine tourne moins vite qu'au moment du chargement du couple, qui n'a agi alors que comme *réservoir*; c'est un *emmagasinement*.

2° Si nous relions un couple secondaire à trois ou quatre éléments Bunsell, et que nous fassions passer ce courant pendant quelques heures, il y aura un seulement *emmagasinement* de travail chimique de la pile arrivant au couple secondaire sous forme d'électricité, mais il y aura *accumulation*, et nous pourrons produire, pendant un temps beaucoup plus court, il est vrai, des effets calorifiques, magnétiques, etc., incomparablement plus puissants que ceux que le courant de la source primitive aurait pu fournir.

Cette propriété précieuse de la pile secondaire a été habilement mise à profit par M. Achard dans son train électrique, dont nous parlerons bientôt, et dans le polyscope de M. Trouvé (voir *la Nature*, n° 297 du 12 juillet 1878, p. 107).

Nous nous sommes signaler ainsi les expériences sur l'électricité de hauteur faites par M. Planté avec huit cents couples chargés à l'aide de quelques éléments Bunsen seulement.

Le nombre des applications des piles secondaires devient immense, sans l'inconvénient que nous devons maintenant signaler. Dans un couple bien formé, l'emmagasinement est limité par la surface des lames de plomb qui constituent leurs électrodes; comme le volume et le poids des éléments dépendent de cette surface même, il en résulte que la pile secondaire, en égard au travail emmagasiné qu'elle peut fournir, est un appareil relativement lourd et encombrant. Ces considérations ont amené MM. Boussion et Thomson à chercher une combinaison nouvelle d'un accumulateur électrique, dans lequel le procédé d'emmagasinement est tout différent.

Appareil Boussion et Thomson. — MM. Boussion

THE ALTERNATING ELECTRIC DISCHARGE.

The alternating discharge apparatus devised by M. Thenard is well adapted to show the shower of electric fire in different gases under various pressures, for the phosphorescent lights, invisible in full day, which illumine the gas placed in the annular space comprised between the two tubes of concentric gas, when analysed with care in the obscurity, always exhibit the character of a shower.

If the phenomenon is very difficult to observe in oxygen, it is, on the contrary, found by M. Hautefeuille and Chappuis to be very easily recognised in fluoride of silicium.

When produced at atmospheric pressure in this substance, the spark has the appearance of a homogeneous luminous sheet. The manifest space is filled with little luminous globules of a greenish yellow hue in darkness, and retarder zone colours in diffused light, the flame of a candle. In examining the tube by a magnifying glass during discharge, we are struck with the analogy which the phenomenon presents with that described by MM. de Monduir and Schuermg in their beautiful experiments on "electric butterflies," where the burning of hydrogen in the air gives lights which recall the silicic snowflakes.

The discharge in fluoride of silicon is exempt at all to study if the distances of the electrified surfaces attain several millimetres, because the luminous points, well separated, show that the successive discharges take place under the form of little luminous cylinders joined to small phosphorescent sheets with circular outlines; so that if the two cylinders are concentric, the central tube seems to be plastered on its exterior surface with regular luminous lines, equidistant, and terminated at the other tube, the whole recalling a mop with luminous tags. If the two cylinders are not concentric, the discharge only passes between the nearest walls, allowing the phenomenon to be studied on the edges. The space seems traversed by a shower of fire, as in the apparatus of M. du Moncel.

A diminution of pressure of the fluoride of silicon does not change the general characters of the discharge; but, in withdrawing the tubes of electrified glass, it can be readily proved that each luminous line is swollen at the ends. With low pressures the luminous drops, instead of designing themselves on a black background, seem hid in a violet mist. At the same time their contours loose their definition. A maximum of splendour is seen in the discharges which occur in the plane passing through the observer and the axis of the apparatus. The cylindrical lines, if dilated in rarefied gases, preserve, nevertheless, a lively splendour when the eye looks along them.

For pressures below 760 millimetres the general illumination masks the shower of fire almost completely—the drops seem to be deep in the mist.

Nitrogen is, after fluoride of silicon, the gas which gives the finest rain of fire. At ordinary pressure the globules—of a pale reddish hue—are very small and very close. The phenomenon of nitrogen to what supports the gas in air. We only obtain a luminous sheet of homogeneous appearance at pressures below 0·050 metres.

Hydrogen exhibits also this form of discharge. At atmospheric pressure the phenomenon in colour is almost identical with that observed in fluoride of silicon at low pressures.

The same appearances are observable with chlorine. The luminous drops are greyish, and much less brilliant than those of fluoride of silicon. This gas, under ordinary pressures, opposes a very great resistance to the passage of electricity. Thick electrified surfaces ought to be very near, for if they are at 0·005 metres, for example, the luminous lines, without having the character of a spark, resemble it in luminous intensity. This small number of luminous lines and the brilliant effects which appear on the surfaces of the walls of the tube, unifying amongst them the successive lines situated sometimes more than a centimetre from each other.

In oxygen the discharge is hardly visible, the gas becomes very slightly luminous, or rather phosphorescent. Nevertheless, on the surface of the concentric tubes, with a magnifying glass, a granulation the gas has not too feeble a tension, the distinct luminous globules can be detected.

The constitution of the milky white lights produced by the alternating discharge in carbonic acid recalls the lights observed in oxygen, but the analysis of them is easier.

These discharges are only silent, in all gases at feeble pressures. They are silent also in hydrogen at atmospheric pressure. The rain of fire is accompanied in other gases by a rustling sound.

Discharge tubes, such as are constructed by M. Abreguiat, will show the rain of fire under its various aspects in different gases under different pressures.

du rayon, nous sommes obligés de donner *à priori* l'une de ces deux variables, si nous voulons que l'action transmise au poste récepteur ait un sens.

Or, l'intensité est déterminée par la source lumineuse elle-même, et nous ne pouvons disposer que du point du circuit où nous placerons l'organe sensible. Nous sommes ainsi forcés de décomposer la lumière en couleurs simples, de transmettre celles-ci individuellement et de les recomposer ensuite...

Maintenant, dans quelle voie peut-on espérer trouver la solution directe de ce problème, que nous avons énoncé sous forme de désidératum?... Ce sera l'objet d'un prochain travail.

Paris, le 2 novembre 1880.

MAURICE LEBLANC,
Ancien élève de l'École polytechnique.

REVUE DES TRAVAUX

RÉCENTS EN ÉLECTRICITÉ

De la Polarisation électrolytique.

M. Exner, dont nous avons analysé plusieurs mémoires, se pose décidément un réformateur de tous les principes physiques admis, et il se trouve actuellement en opposition avec presque tous les physiciens.

Nous avons vu qu'il a nié la force *électro-motrice de contact*, malgré tous les travaux importants faits dans ces derniers temps dans cet ordre d'idées. Nous avons vu encore que les couranx thermo-électriques ne sont pour lui que des courants résultant d'actions chimiques, hypothèse qui a été facilement renversée par les expériences de M. Young, et voilà maintenant que les effets de polarisation électrolytique ne sont plus le résultat d'une force électro-motrice secondaire, créée à la suite des réactions des produits de la décomposition. La encore il se trouve attaqué par M. Fitz-Gérald, et non sans raison. Nous savons bien que les effets de polarisation ont diverses causes, mais il est bien difficile d'admettre qu'avec sa manière de voir on puisse les expliquer d'une manière générale.

Pour qu'on puisse comprendre la théorie de M. Exner, il faut savoir que, suivant lui, il ne peut y avoir de force électro-motrice de produite dans un générateur électrique, qu'autant qu'il s'y manifeste une action chimique, et que l'importance de cette force *dépend de la chaleur qui est alors développée*. Or, si les produits décomposés par suite de l'action électrolytique se combinent de manière à constituer d'autres corps, il doit y avoir une quantité de chaleur absorbée, et cette quantité de chaleur étant empruntée à la chaleur primitivement dégagée, abaisse d'autant la valeur de la force électro-motrice primitive, et détermine par conséquent l'affaiblissement du courant qui en est la conséquence. Voilà, suivant M. Exner, *ce qui constitue les effets de polarisation, et son la création d'une force électro-motrice contraire* sur les électrodes où se produisent les décompositions primitives.

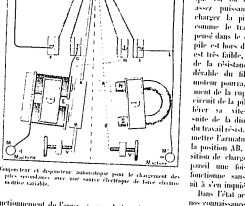
M. Desmond G. Fitz-Gerald fait remarquer que cette déduction de M. Exner conduit à des résultats tout à fait contraires à ceux de l'expérience, et voici ce qu'il dit à cet égard dans l'*Electrician* du 9 octobre 1880 :

« Si, ainsi que l'admet M. Exner, l'on électrolyse est décomposée dans un élément Bunsen ou Grove, ou dans un élément de Smée, il est certain qu'avec les premières piles, l'eau décomposée est reconstituée aux dépens de l'acide nitrique par oxydation, tandis que, dans la dernière pile, l'hydrogène se dévelope entièrement sans reconstitution antiséquente. Or, d'après le principe de M. Exner, la chaleur due, dans le premier cas, à la combinaison de l'hydrogène avec l'oxygène de l'acide nitrique, devrait être soustraite de celle résultant de l'oxydation du zinc et de celle déconnitée par suite de la solution de l'oxyde formé dans l'acide nitrique dilué, pour obtenir la force électro-motrice du couple de Grove ou de Bunsen. Dans le cas de la pile de Smée, cette force électro-motrice serait simplement accrue par la chaleur développée dans les deux dernières actions mentionnées précédemment, sans aucune soustraction; d'où il résulterait que la force électro-motrice d'un élément de Smée serait beaucoup plus grande que celle d'un élément Bunsen ou Grove, et que le développement libre d'un corps électro-positif énergique tel que l'hydrogène, serait le résultat d'un grand accroissement de force,

« Ce qui démontre encore que la thèse soutenue par M. Exner n'est pas exacte, c'est que, dans une autre partie de son mémoire, il est en contradiction complète avec ce qu'il annonce au commencement, et pose des principes contraires aux lois électro-chimiques qui servent de base au développement de la force électro-motrice dans un couple voltaïque : « Dans une pile de Daniell, dit-il, dont la force « électro-motrice est prise comme unité d'oxydation d'un « équivalent de zinc, il se développe jusqu'à 24,300 calo- « ries (1), et cette chaleur donne la force électro-motrice de « cet élément. Dans un autre élément, celui de Smée, par « exemple, les actions chimiques sont un peu différentes : « le zinc se combine avec l'oxygène de l'eau, et l'oxyde de « zinc ainsi formé se combine avec l'acide sulfurique. Or « ces deux actions chimiques développent 32,370 calories « par équivalent de zinc. Si, par conséquent, il n'y avait pas « d'autres actions chimiques développées dans un élément « de Smée, les forces électro-motrices de cet élément et de « celui de Daniell seraient entre elles comme 24,300 : 32,370. « soit comme 1 : 2,24. Mais l'eau se trouve décomposée et « cette décomposition représente une perte de chaleur de « 34,170 (24,180) calories par équivalent; de sorte que la « perte effective de chaleur n'est que de 17,800 calories, et le « véritable rapport entre les éléments Daniell et Smée est « comme 24,300 : 17,800 ou comme 1 : 0,732. Si on « expérimente, on ne trouve pas d'abord ce rapport, car « au commencement, l'élément de Smée est toujours plus

(1) L'oxydation de l'équivalent de zinc (32,7 grams) dégagerait 2 pen près 23 100 calories.

combiné, il n'y a plus *consommation*, mais au contraire *dépense* d'électricité : la pile se décharge dans la machine pour aider son mouvement, dépense inutilement la charge primitivement accumulée et exposant ainsi la pile secondaire à se trouver complétement déchargée au moment même où l'on a besoin de ses services. Pour remédier à cet inconvénient, nous intercalons dans le circuit qui relie la pile secondaire à la machine, l'appareil représenté ci-dessous, et qui est un disjoncteur et conjoncteur automatique. Il a pour effet de couper le circuit lorsque la machine ne tourne plus assez vite pour charger la pile et de rétablir lorsque la force électromotrice de la machine, par suite d'une augmentation de vitesse, est redevenue assez grande pour réfléchir de nouveau le chargement.



Coupe-fort et disjoncteur automatique pour le chargement des piles secondaires avec une source électrique de force électromotrice variable.

L'appareil se compose d'un électro-aimant E, devant lequel se meut comme un pendule une armature AB, dont les vis V, V limitent la course.

La tige de suspension porte un bouton d'ivoire B, qui dans la position AB, établit un contact en C, et dans la position A'B' établit un contact en C'. L'électro-aimant E porte deux fils, un fil gros et court formant le circuit MEGCFM, un fil fin et long formant le circuit MEHCLM'.

La machine est reliée aux bornes M et M', la pile secondaire aux bornes P et P'.

Voyons maintenant le fonctionnement de l'appareil.

Supposons que la machine tourne à une vitesse normale, et que l'armature soit en AB. Le courant de la machine arrivant en M traversera le gros fil de l'électro-aimant, le contact C, la pile secondaire placée entre P et P' et retournera à la machine par P'F et le second fil attaché à la borne M'.

Le courant étant assez intense pour charger la pile, maintiendra l'armature AB en place. Si la machine se ralentit, le courant de charge diminuera, et lorsqu'il sera devenu nul, l'armature AB sera lâchée, retombera et se placera dans la position A'B' sous l'action du petit aimant permanent NS. Dans cette position, le contact C sera ouvert et le circuit de la pile secondaire et de la machine rompu en ce point, mais le contact C' sera fermé par le même mouvement. Le courant de la machine traversera donc le *fil fin*, les bans HC' et C'L, et retournera à la machine par HM. Il en résultera une aimantation de l'électro-aimant E, aimantation qui dépendra de la force électromotrice de la source. En réglant l'appareil à l'aide de la vis V et de l'aimant permanent NS, qu'on peut changer ou rapprocher à volonté, de telle sorte que l'électro-aimant attire l'armature AB lorsque la force électromotrice du courant fourni par la machine est assez grande pour charger la pile secondaire, l'armature quittera la position A'B' pour prendre la position AB à ce moment même, et remettra la pile dans le circuit de la machine, et ainsi de suite. L'appareil se met donc automatiquement dans la position AB ou dans la position A'B', suivant que la source électrique est ou n'est pas assez puissante pour charger la pile. Mais comme le travail dépensé dans le cas où la pile est hors du circuit est très faible, à cause de la résistance considérable du fil fin, le moteur pourra, au moment de la rupture du circuit de la pile, accélérer sa vitesse par suite de la diminution du travail résistant exercé par l'armature dans la position AB, ou par suition de charge. L'appareil une fois réglé fonctionne sans qu'on ait à s'en inquiéter.

Tel est l'état actuel de nos connaissances, l'acumulation du travail par la pile secondaire de M. Planté et l'utilisation des forces naturelles par l'électricité, pour recevoir des applications dont le nombre s'accroîtra de jour en jour, à mesure qu'on augmentera la capacité spécifique de l'accumulateur.

Le moteur électrique est la plus simple des machines motrices : il suffit de deux fils pour les amener le courant qui l'actionne; un simple commutateur suffit pour le manœuvrer. Il y a donc là une série d'avantages que l'on appréciera bien, le jour où, par une disposition rationnelle de distribution et d'accumulation de l'électricité à domicile, on amènera chez chacun la lumière et la force motrice.

E. HOSPITALIER.

CONCENTRATING OR STORING UP ELECTRICITY.

Several years ago M. G. Planté, of France, made a secondary electrical battery, in which the electrical power of several ordinary cells could be concentrated or stored up within one cell, and the electrical force so gathered could be used when wanted. This battery consisted of two electrodes made of sheet lead, separated by strings of rubber, and placed in dilute sulphuric acid.

To charge this battery the poles were connected with an ordinary Bunsen or Daniell cell. During the operation of charging, one of the electrodes oxidizes, a brown coating of peroxide of lead soon showing itself thereon, and the metallic appearance disappears entirely; the other electrode also changes in appearance, its surface becoming covered with a powdery gray coating. When thus charged the secondary battery was capable of delivering an electric current of very much greater force than an ordinary cell of same size. This secondary battery is capable of charge and discharge indefinitely. M. Planté has lately improved upon the Planté battery, by pasting the lead sheets with red lead. Simple as the improvement is, the resulting effects are quite remarkable, the storing capacity and delivery of the battery being greatly increased. The chemical action that takes place in subsequently the same as in the original Planté battery.

It is stated that one of M. Planté's secondary batteries, weighing 165 pounds, is capable of delivering a force equal to one horse power during a period of one hour. If this is so it would bring the weight of an electrometor and battery of one horse power within a gross weight of 200 pounds, and suggests, as one of the possibilities of the new discovery, the production of a carriage propelled by electricity, convenient and economical in use.

For the benefit of those who desire to try this interesting electrical contrivance, we give on another page an illustration in explanation of some recent ingenious experiments on the subject lately made in our office. Any intelligent person who has at hand a few sheets of lead may readily construct the new battery.

Professor Sir William Thomson, of Glasgow University, who has lately experimented with these new batteries, mentions the use of one of the cells, weighing 18 pounds, which Professor George Buchanan took with him in his carriage and successfully employed in removing a tumor from a child's tongue by heating a platinum wire. The bureau published the same effect by the ordinary electrical means would have required the putting in of several voltaic cells, and involved much inconvenience. Professor Thomson anticipates that this method of storing electricity will have many practical uses. He sums as follows:

"The largest useful application is waiting just now for the Faure battery, and I hope that a very minimum time will be allotted to pass until the battery comes into daily application is to do for electric light what a water cistern in

is house does for an inconstant water supply. A little battery of several dozen cells is to give the brush-comes to the Swan or Edison lights to the extent of one hundred candles for six hours without any perceptible diminution of brilliancy. Thus, instead of needing a gas engine or steam engine to be kept at work as long as the light is wanted, with the liability of the light failing at any moment through the slipping of the belt or any other breakdown or stoppage of the machinery, and instead of the wasteful inactivity during the hours of the day or night when the light is not needed, the engine may be kept going all day and stopped at night, or it may be kept going day and night, which undoubtedly will be the most economical plan when the electric light comes into general enough use.

"Another very important application of the accumulator is for the electric lighting of steamships. A dynamo-electric machine of very moderate magnitude and weight, driven by a belt from a drum on the main shaft, working through the twenty-four hours, will keep a Faure accumulator full, and thus, notwithstanding the irregularities of the speed of the engine at sea, or the occasional stoppages, the supply of electricity will always be ready to feed the Swan or Edison lamps in the engine rooms and cabins, or are fields for the mast-head, and red and green side lamps, with more certainty and regularity than have yet been achieved in the gas supply for any house on *terra firmæ*."

English Mechanic Sept 24th 1880

[44937.]—**The Faure Battery.** The current given out is of course proportional to the current which is put in. We also involve a consideration of time. But the question as to cells ought to no greater than that of time. Thus, a cell using two ounces of zinc for charging is doubtless more efficient than one using more cells in series than will give the same current the electro-motive force of the secondary cell itself. Question 3 cannot be answered, because the answer in any case depends on the conditions. The proper thing to do is to insert in the connections a galvanometer, an ammeter, and study its readings. As the charge goes on the galvanometer will show diminishing current, and when it is zero the continuous current ceases, and shows the charge is complete. If an overpowerful generator is used, the continuous current may be large, because decomposition will go on, producing oxygen and hydrogen gases, which escape and be wasted. The acid must not be put strong; in fact, it cannot, because the mass of solution, if strong, will corrode metals, and the cost of the acid will be an object. There will be local action, and great loss of charge, unless other people get better results than I have.—EDITOR.

Notre Sujet Le Chemin de Fer Supplement.

A TRIAL OF THE ELECTRIC LIGHT AT CLERKENWELL.—A correspondent, residing in the neighborhood, sends us the following:—"The Fine Arts and Industrial Exhibition, which will be held in Corlitt during the next two months, was duly opened on Friday last by the Mayor of the town. The exhibition is in the Drill Hall—a very large and elegant structure. Among the many objects of special interest, for the public, one of the most attractive features of the display, and, as a matter of course, great things were expected. Of the use of the electric light, and the effect of a large number, the fittings of each being elaborated and rendered very beautiful in appearance. The electric lights inside the hall were most brilliant and pleasant so long as they kept in working order. About nine o'clock, however, they became suddenly extinguished; and refused to be resuscitated, to the disappointment of many friends and admirers. In this unlooked-for crisis, the despised gas was called in, and intended should be discarded for this amplifier of modern, but it was soon found that the failure of the electric fluid, during character, immediately restored to the position it once occupied. many objects of interest, which, through the failure of the electric light, had been so peremptorily shrouded in darkness. For illuminating purposes, gas has to stand on its merits, no relays of candles or oil lamps being at hand to assist it, as was the case at a moments' notice, should a similar failure overtake a gas supply."

ELECTRIC STORAGE OF DYNAMICAL ENERGY.

TO THE EDITOR OF THE TIMES.

Sir,—The marvellous "Lex of electricity" described in a letter to you, which was published in *The Times* of May 16, has been subjected to a variety of trials and measurements in my laboratory for nine days' weeks, and I think it may interest your readers to learn that the results show your correspondent to have been by no means too enthusiastic as to its great practical value. I am continuing my experiments to learn the behaviour of the Faure battery in varied circumstances, and to do what I can towards finding the best way of arranging it for the different kinds of work to which it is to be applied. At the request of the Council of Administration of the Société des Forces et la Lumière, I have gladly undertaken this work, because the subject is one in which I feel intensely interested, seeing in it a realisation of the many ardently and unceasingly felt scientific aspirations of my life—an aspiration which I recently dared to express or to hope to live to see realised.

The problem of converting energy into a preservable and storable form, and of laying it up in store conveniently for allowing it to be used at any time when wanted, is one of the most interesting and important in the whole range of science. It is solved on a small scale in a common watch, in drawing a gun cuplon or steam engine to be kept at work as long as the light is wanted, with the liability of the light failing at any moment through the slipping of a bolt—an accident of too frequent occurrence—or any other breakdown or stoppage of the machinery, instead of the wonderful self-activity during the hours of day or night when the light is not required, the engine may be kept going all day and night, and when, as there may be kept "going day and night," which will undoubtedly be the most economical plan when the electric light comes into general use, it might be the Faure accumulator, always kept charged from the engine by the home supply wire, with a proper automatic stop to check the supply when the accumulator is full, will be always ready at any hour of the day or night to give whatever light is required. Precisely the same advantages in regard to the force will be gained by the accumulator when the electric town supply is, as it surely will be before many years pass, regularly used for turning lathes and other machinery in workshops and sewing machines in private houses.

Another very important application of the accumulator is for the electric lighting of steamships. A dynamo-electric machine of very moderate magnitude and expense, driven by a belt from a drum on the main shaft, working through the 24 hours, will keep a Faure accumulator full, and then, notwithstanding irregularities of the speed of the engines at sea or occasional stoppages, the supply of electricity will always be ready to feed Swan or Edison lamps in the engine-room and cabins, or arc lights for mast-head and red and green side lamps, with more certainty and regularity than have yet been achieved in the gas supply for any house on *terra firma*.

I must apologise for trespassing so largely on your space. My apology is that the subject is exciting great interest among the public, and that even so slight an instalment of information and suggestions as I venture to offer in this letter may be acceptable to some of your readers.

I remain your obedient servant,

WILLIAM THOMSON.

The University, Glasgow, June 8.

quite certain that it solves the problem of storing electric energy in a manner and on a scale useful for many important practical applications. It has already led in this country one interesting application, of the smallest in respect to dynamical energy used, but not of the smallest in respect to beneficence, of all that may be expected of it. A few days ago my colleagues, Professor George Buchanan, carried away from my laboratory one of the lead cells (weighing about 26lb.) in his carriage, and by it ignited the thick platinum wire of a galvanic *cautere* and bloodlessly removed a mucoid tumour from the tongue of a young boy in about a minute of time. The operation would have occupied over ten minutes if performed by the ordinary chain *cautere*, as it must have been had the Faure cell not been available, because in the circumstances the surgical electrician, with his paraphernalia of voltaic battery to be set up beforehand, would not have been practically admissible.

The largest useful application awaiting just now for the Faure battery—and it is to be hoped that the very minimum of time will be allowed to pass till the battery is supplied for this application—is to do for the electric light what a water cistern in a house does for an intermittent water supply. A little lantern of seven of the boxes described by your correspondent suffices to give the incandescence in Swan or Edison lights to the extent of 100 candles for six hours, without any perceptible diminution of brilliancy. Thus, instead of needing a gas engine or steam engine to be kept at work as long as the light is wanted, with the

ELECTRIC STORAGE OF DYNAMICAL ENERGY.

TO THE EDITOR OF THE TIMES.

Sir,—Although agreeing with every word of Sir William Thomson's letter in *The Times* of to-day, and entirely sympathising with the enthusiasm as regards the marvellous but of electricity, still I feel that it would have been desirable if in pointing out the importance of this new discovery Sir William Thomson had guarded against a very probable misconception of the purport of his letter.

The means of storing and re-storing mechanical energy form the aspiration not only of Sir William, but of every educated mechanic. It is, however, a question of degree—of the amount of energy stored as compared with the weight of the reservoir, the standard of comparison being coal and coal. Looked at in this way, one cannot but ask whether, if this form of storage is to be the realisation of our aspirations, it is not completely disappointing. Large numbers are apt to create a wrong impression until we inquire what is the unit. Eleven million foot pounds of energy is what is stored in 1lb. of ordinary coal. So that in this use, weighing 70lb., there was just as much energy as in 1jac. of coal, which might have been brought from Paris or anywhere else in a waistcoat pocket, or have been sent by letter.

When we come to the question of the actual conveyance of energy for mechanical purposes, this view is of fundamental importance. The weight of the same amount of energy in the new form is 600 times greater than the equivalent amount of coal; and as a matter of economy, supposing that energy in this form might be had at a certain spot and as capital were required for the conversion or storage, and that the energy were directly applicable it could not be carried ten miles—that is to say, such energy cannot be economically useful ten miles from its source, although coal had to be carried 100 miles to the spot. This limit, in truth, falls far short of what has been already attained by other means. By wire waves and by compressed air or steam energy may be economically transmitted from 10 to 20 miles. So that if this is the utmost of what is to be done by means of the storage of electricity this discovery adds another door to those which are heavily closed against the possibility of finding in Niagara or other water power a substitute for our coal, even when the object is native power, and much more for that purpose for which five-sixths of our coal is used—the production of heat.

It is very important that the people of this country should not shut their eyes to the fact that so far from there being a greater prospect of the solution of the problem than when, about 20 years ago, Professor Jevons raised the alarm, the prospect is now much smaller. In the meantime the capabilities of steel rapes, fields in pipes, and electricity along conductors have been not only hinted, guided, but practically tested and found altogether wanting. And now it would seem that the storage of electricity must be added to the list.

I remain, yours obediently,

OSBORNE REYNOLDS.

Owens College, June 9.

2

ELECTRIC TRANSMISSION OF ENERGY.

TO THE EDITOR OF THE TIMES.

Sir,—Your leading article in the *Times* of yesterday on the storage of electricity alludes to my having spoken of Niagara as the natural and proper chief motor for the whole of the North American Continent. I value the allusion too much to let it pass without pointing out that the credit of originating the idea and touching how it is to be practically realized by the electric transmission of energy is due to Mr. C. W. Siemens, who spoke first, I believe, on the subject, in his presidential address to the Iron and Steel Institute in March, 1877. I myself spoke on the subject in support of Mr. Siemens's views at the Institution of Civil Engineers a year later. In May, 1879, in answer to questions put to me by the Select Committee of the House of Commons on Electric Lighting, I gave an estimate of the quantity of copper conductor that would be suitable for the economical transmission of power by electricity to any stated distance; and, taking Niagara as example, I pointed out that, under practically realisable conditions of intensity, a copper wire of half an inch diameter would suffice to take 25,000-horse power from water wheels driven by the Fall, and (*inter alia*) 20 per cent. on the way) to yield 21,000-horse power at a distance of 300 British statute miles; the price cost of the copper amounting to £60,000, or less than £3 per horse power actually yielded at the distant station.

I remain, Sir, your obedient servant,

WILLIAM THOMSON.

The University, Glasgow, June 8.

[In the second sentence of the third paragraph of Sir William Thomson's letter published in *The Times* of June 9, for "in own laboratory letter," substitute "my own laboratory letter."]

TO THE EDITOR OF THE TIMES.

Sir,—Professor Osborne Reynolds's letter in your issue of Saturday, the 11th inst., shows that the first idea that has occurred to him on reading Sir William Thomson's letter on Faure's "electric store" is probably what must have suggested itself to many engineers—viz., that as far from a million foot pounds being a surprisingly large amount of energy to be stored up in a mass of 70lbs., it is really extremely small; and, indeed, while crossing over from Paris at the commencement of last week, I could not help thinking that the passengers were belaging to England literally in the smoke and blacks on their seats far more energy than had ever been imported into this country stored up in Faure's secondary batteries. But although it is perfectly true, as Professor Reynolds says, that 1jac. of coal contains about one million foot pounds of work stored up in it, this is by no means all that has to be taken into account in considering this question; for where is the engine for extracting this million foot pounds of work out of the 1jac. of coal? Indeed, as Professor Reynolds would

himself tell us, we cannot get much more than one-tenth of this amount of work out of the lips, of coal even in our largest steam engines, which burn many pounds of coal per minute, and in which much heat has been wasted in getting up steam. And if we come to the burning of one single lump, of coal, I know of no engine that can obtain from this even one thousand foot pounds of work, or one thousandth of the energy contained in the coal, if no other coal be used in getting up steam or in previously heating the engine.

But if a secondary battery be allowed to drive a magneto-electro-motor or a dynamo-electric machine with separate exciter only once for the short time necessary to develop, say, 20 foot pounds of mechanical work, I maintain this can be done without using up in the whole process more than about 25 foot pounds of the electric energy stored up in the reservoir, since the expensive acts of Prometheus and Vulcan have shown that, when the motor is running at high speeds with a light load, as much as 93 per cent. of the electric energy put into a magneto-electro-motor is given out again as mechanical work measured by absorption dynamometer.

It may be answered, however, that if a small bit of coal, although containing a vast store of energy, is not of much practical use in producing work in consequence of the shortness up to the present time of a proper converter of the coal's energy into mechanical work, at any rate a small galvanic battery (a little Daniell's cell, for example) is not only a vast storehouse of power, but contains a store which we have the means of converting without appreciable loss into electric light or mechanical work. Here, then, is a Faure's but a better store of electric energy than a little Daniell's cell? This question has precisely the same answer as "Why is a pinch of dry gunpowder better than a pound of wet?" Not because the dry gunpowder has more energy in it than the wet, but because the energy stored up in the dry gunpowder can be all, if we wish, used up quickly, and an explosion produced, whereas that in the wet can only be utilised bit by bit. So seven Faure's boxes will illuminate 100 lamps for six hours, while seven Daniell's cells, or, indeed, twice that number, although possessing a store of power millions of times as great as that in the Faure's boxes, will not illuminate a single lamp light.

But while fully recognising the great advance made in the subject by Plantè, and the recent improvements introduced by Faure, I do not wish to give the impression that the problem is by any means completely solved, since, for the attempt that Mr. Perry and myself, no doubt like many other electricians, are making to convert at a low temperature the energy in coal into electric energy meets with even a fairly satisfactory solution, then a bagload of coals, will be a practical store of energy of incomparably greater value than the secondary battery.

A MIGHTY POWER.

Compressed Electricity Rivetting the Improvised Genie to its Bottle.

THE FRENCH STARTING CABLE TO THE NEVADA TELEGRAM.

LONDON, May 17.—Sir Williams Thomson, F. R. S., of the University of Glasgow, has received from M. Camille Faure, of Paris, the discoverer, a box of "electric energy." A gentleman writes to the *Times* this morning as follows:—"On Monday last, in Paris, a Faure battery or *pile accumulatrice* was charged with the electric fluid, direct from an ordinary Grove battery, by my permission. The receptacle consisted of four Faure batteries, each about five inches in diameter and ten inches high, forming a cylindrical leaden vessel and containing alternate sheets of metallic lead and absorbent, wrapped in felt and rolled into spirals wetted with acidulated water, and the whole placed in a square wooden box, measuring about one cubic foot, and weighing some seventy-five pounds. This was protected by a loose wooden cover through which the electrodes in lead protruded and were fastened down for the convenience of transportation. This box of electric energy was handed to me by M. Faure with the object of submitting it to examination and measurement at the hands of Sir William Thomson.

CARRIED TO SCOTLAND INTACT.

"In about seventy-two hours from the time of charging the jar in Paris I had the satisfaction of presenting Faure's rare discovery of a box of electricity intact. This is the patent compressed form within the small space of one cubic foot of a power equivalent to nearly one million feet. The wonderful box is now deposited in the laboratory of Glasgow University and is being submitted to a series of tests and measurements. The results of some of these made Sir William exclaim, 'Why, it's a little giant!' The advantages to science and humanity which this discovery, or rather the perfection of Plantè's discovery is destined to afford, are of such transcendent importance that we cannot for the present form any correct estimate of its magnitude. Whatever may be the practical results obtained I have the satisfaction of recording that for the first time in my knowledge in the history of the universe a box of electric energy nearly equivalent in a million feet contained within less than a cubic foot of space, latent and potential, has been transported from France or elsewhere to Great Britain."

The facts about the omnibus, or rather tramcar, recently driven by means of a Faure battery in Paris, are coming out gradually, and they do not improve on a nearer acquaintance. In the first place, the battery, with its 100 accumulators, cost 20,000 francs, with its 100 accumulators, cost 20,000 francs, with its 100 accumulators, cost 20,000 francs

himself tell us, we cannot get much more than one-tenth of the amount of work out of the line of coal even in our largest steam engines, which burn many pounds of coal per minute, and in which much heat has been wasted in getting up steam. And if we come to the burning of one single lump, of coal, I know of no engine that can obtain from this even one thousandth part pounds of work, or one thousandth of the energy contained in the coal, if no other coal be used in getting up steam or in previously heating the engine.

But if a secondary battery be allowed to drive a magneto-electro-motor or a dynamo-electric machine with separate exciter only even for the short time necessary to develop, say, 20 foot pounds of mechanical work, I anticipate this can be done without using up in the whole process more than about 25 foot pounds of the electric energy stored up in the reservoir, since the experiments of Professor Ferry and myself have shown that, when the motor is running at high speeds with a light load, as much as 62 per cent. of the electric energy put into a magneto-electromotor is given out again as mechanical work measured by an absorption dynamometer.

It may be answered, however, that if a small bit of coal, although containing a vast store of energy, is not of much practical use in producing work in consequence of the slowness up to the present time of a proper conversion of the coal's energy into mechanical work, at any rate a small galvanic battery is little Daniell's cell, for example) is not only a very inefficient source of power, but contains a store which we have the means of converting without appreciable loss into electric light or mechanical work. How, then, is Mr. Ferry's box a better store of electric energy than a little Daniell's cell? This question has precisely the same answer as "Why is a pitch of dry gunpowder better than a pitch of wet?" Not because the dry gunpowder has more energy in it than the wet, but because the energy stored up in the dry gunpowder can be all, if we wish, used up quickly, and so explosion produced, whereas that in the wet can only be utilized bit by bit. So seven Ferry's boxes will illuminate 100 Swan lamps for six hours, while seven Daniell's cells, or, indeed, twice that number, although possessing a store of power millions of times as great as that in the Ferry boxes, will not illuminate a single Swan light.

But while fully recognising the great advance made in the subject by Planté, and the recent improvements introduced by Faure, I do not wish to give the impression that the problem is by any means completely solved, since, if the attempt that Mr. Ferry and myself, no doubt like many other electricians, are making to convert at a low temperature the energy in coal into electric energy meets with even a fairly satisfactory solution, then a fragment of coal, or, it may be, a puff of gas (or, in nature, of carbonic oxide), will be a practical store of energy of incomparably greater value than secondary batteries.

W. E. AYRTON.

A MIGHTY POWER.

Compressed Electricity Rivalling the Supernatural Genie in the Bottle.

VIA FRENCH STATION CALAIS TO THE EVENING TELEGRAPH.

London, May 17.—Sir William Thomson, F.R.S., of the University of Glasgow, has received from M. Camille Faure, of Paris, the discoverer, a box of "electric energy." A gentleman writes to the *Times* this morning as follows:—On Monday last, in Paris, a Faure battery or pile accumulator was charged with the electric fluid, direct from an ordinary Grove battery, in my presence. The receptacle, about inches in diameter and ten fee a cylindrical leaden case, ternate sheets of metallic lea wrapped in felt and rolled in with sulphuric water, and the a square wooden box, measu cubic foot, and weighing a pounds. This was protected b cover through which the electr leaded and were flattened do continuance of transportation. Th tric energy was handed to me b the object of submitting it to e measurement at the hands Thomson.

CABBITO TO SCOTLAND

Faure's Secondary Battery

In your issue of last week you gave an account of the *soirée* held at King's College, London, on the evening of July 2, and in this account it is stated that "the great event of the evening was the publication for the first time in England of M. Faure's *secondary* battery."

At the *soirée* given by the Mayor of Nottingham on the evenings of June 30 and July 2 in connection with the opening of the College by H.R.H. Prince Leopold, I had the pleasure of exhibiting to large audiences one of M. Faure's new batteries. Sheets of lead were cast by into the form of shallow trays, one foot square and one inch deep; in each of these was placed a layer of red lead, then a layer of flannel, then a layer of red lead, and lastly another lead plate. These trays to the number of six were then piled one above the other, and the whole filled with dilute acid. The cells being connected in series, were polarized by a 10 cell battery of Grove's cells, and after twenty minutes' charging, had taken up a very large quantity of electricity. At a short interval given during the evening the charged Faure battery was connected with a Gramme machine, and drove it round with great velocity for some minutes. After this employing the rest of the charge the remainder was used for heating several inches of platinum wire, and for driving for a few seconds a simple form of magneto-electric engine. These experiments amply convinced me of the practical character of M. Faure's invention. As I have had also the opportunity of examining one of the original batteries of the inventor, I was obliged to make up this experimental form. It is hoped to be exhibited for lecture-room demonstration, as it permits the construction of the battery to be exhibited to an audience. The enormous superiority of M. Faure's cell over the old form of Planté cell is evident at once on experimenting with it. J. A. FLEMING

The University College, Nottingham, July 10

Elec. Rev. June. 18. 1881

SIR W. THOMSON has been experimenting with M. Faure's accumulator, or secondary battery, and is now enabled to give us some approximate results showing the real value of the invention. A Faure battery weighing about 1920lb will store sufficient energy to give out one hours-power during an hour, or two million foot-pounds. As to the useful effect—the proportion of energy given out as compared with that stored up in the battery—Sir W. Thomson is unable at present to speak positively, but when the accumulator is employed under conditions conducive to economy the loss of energy is less than 10 per cent. Put into a practical form, the calculations show that accumulators weighing three-quarters of a ton would yield a one-horse power during six hours, or if the accumulators weigh only one-quarter of a ton they would yield the same still of a horse-power during six hours. If these estimates are correct, a tramcar could run three hours on one hour by a Faure battery weighing less than eight hundredweight—a result which has not been known, but this point experiment alone can determine, but the great weight of the battery is a serious objection to the new motor. Where the Faure battery system can be adopted it is clear that the Faure battery has a very distinct field for tramway work, at all events. Another disadvantage is that the Faure accumulators can only be charged by a dynamo machine—only by ordinary forms of battery—so that the electrical energy is expensive in first cost. M. Planté, the real inventor of the secondary accumulator, has taking advantage of this fact to show that his device is really more economical than the newer modification; for his battery can be charged by a magneto-electric machine. He is constructing such an accumulator on the original form for M. Lissadelor, which is to work a small balloon, and which will be exhibited at the forthcoming International Electrical Exhibition. Edison will probably turn his attention to the subject, and with the unrivalled resources of his laboratory we may fairly expect that, before the century is out, a reliable storage in electricity as a motive power will be made. *Echo* June 16/81

PLANTÉ AND FAURE BATTERIES.

THE annexed illustrations of the secondary batteries, which are exciting so much interest at the present time will, with the accompanying description, enable the reader to understand their construction. At the recent soirée given by the Council and academical staff of King's College, several forms of electric lighting apparatus were used; but that which attracted most attention was a battery of forty-four accumulators of Faure's design, working twenty of Swan's lamps. These cells were charged in Paris by a Gramme machine, and were arranged in groups of four in cabinet boxes, the whole being coupled up in series. The current supplied by this arrangement, shown by a galvanometer in the circuit while the lamps were alight, was about twenty-seven webers, and was perfectly steady, the Faure battery yielding an almost equal current during the whole time, until the charge became exhausted, when it broke down suddenly, without any perceptible warning. Mr. Spottiswoode also uses the Faure battery to work Swan's incandescent lamps in his private house. Figs. 1 to 3 represent the Planté cell. The preparation is as follows:—Two sheets of lead (it may be as thin as stout lead-foil) are laid the one on the other, separated by two strips of indiarubber, the whole being rolled up as shown in Fig. 1. The roll having been completed, the cylinder is placed in its formation in withdrawn, and it is occasionally by a wrapper of gutta-percha, and inserted in a glass jar filled with water and 1-10th part acid. An electric current is then made to pass through the cell; oxygen is given off, and peroxide of lead is deposited on the surface of the sheet in the left-hand series of cells at the other sheet. The jar is then filled with dilute acid that has been diluted with water, and the two sheets are connected, a current will be produced, owing to the presence of the oxygen, which leaves the sheet where it has accumulated, and attacks and oxidizes the other sheet. This secondary current, which is very small at first, gains strength each time the operation is repeated; in time the surfaces of the sheets are changed, the one being covered with a coating of peroxide of lead, the other with lead reduced to a spongy mass. The cell is then complete, and is in a state of electrical accumulation. This was Planté's first discovery. Subsequently he tried the plan of separating the two sheets of lead by canvas, the cell taking the form of Fig. 2. He then found that it was necessary to have a small space between the sheets to provide for the escape of the gases which were produced at the end of the charge; subsequently indiarubber bands were employed in preference to canvas. M. Planté then tried carbonate of lead, minium, &c., but without answering upon the results already obtained. The Faure battery is made in the form shown:—Two sheets of lead are taken, about 7½in. wide, some 12in. long and about 1-25th of an inch thick, the other 10in. long and 1-16th. thick. Each sheet is covered over with a strong sheet of lead, one of its ends. Each sheet has a layer of red-lead paste on its and is rolled up with a piece of indiarubber, the lead being made into paste with water, the longer sheet having a little more grittiness on its surface, and the smaller 700 grammes. On each surface a sheet of perforated lead, and the whole is introduced into a sheathing of thick felt. The sheets are laid one above the other; at the same time several bands of indiarubber are placed in an oblique fashion, as shown in Fig. 3. The roll is pressed in a broken jar, strengthened by copper bands, and placed in the interior with red lead and felt. They cell then presents the appearance shown in Fig. 4. One of the pieces of lead which jut out is bent and soldered in the outer jar, solidified water is put in, and the battery is ready for work.

We give the above figures as a guide, but there is no special reason for adhering to them, as they may be doubled whether either the paste-coated or felt is an absolute necessity; for equal battery can be made by simply painting the stout lead-foil with red-lead made into paste with water slightly acidified with oil of vitriol, and wrapping the plates in flannel or canvas which has been previously coated with red-lead paint. The painted surfaces are put one to come put together. This lead is used to keep the weight down as much as possible and to reduce the cost.

The storage of electricity is progressing, and we learn now that Mr. Brush has also invented a secondary battery, which is reported to be far superior to the Faure. No details of the invention have yet been published, in which he contends that compressed air is the most economical method of storing force. For locomotive purposes, he says, the results obtained from the storing of electricity do not approach those obtained from the storage of air, in the amount of force actually available for traction or propulsion. For tramways, he declares that the cost of air would be considerably below that of steam, while on such a railway as the Underground, the daily pressure of working by air instead of by steam would be little, if at all, in excess, though the first cost would be greater. If that is true, the directors ought to welcome the air-locomotive, as it will help to free the tunnels of their noxious gases.

The Scientific Mechanic and Patent Record, No. 1.

PORTABLE ELECTRICITY.

By the wonderful invention of M. Camille Faure, of Paris, there is compressed within a portable package of one cubic foot an electric energy equal to a million feet. This package consists of four Faure batteries, each about five inches in diameter and ten inches high, forming a cylindrical leaden vessel, and containing thereon sheets of metallic lead and antimonium, wrapped in felt and rolled into spirals wetted with acidulated water, the whole placed in a square wooden box measuring about one cubic foot, and weighing about seventy-five pounds. It is protected by a loose wooden cover, through which the electrodes in lead protrude. One of these packages was recently sent from Paris to Sir William Thomson, at the Glasgow University. After some seven tests and experiments, Sir William exclaimed, "Why, it is a little giant."

THE ELECTRICIAN, MAY 28, 1881.

THE EFFICIENCY OF SECONDARY BATTERIES.

The performance of secondary batteries comprises two phases, the charge of the accumulator by the action of an external source, and its discharge in the working circuit. Now, each of these operations involves a certain loss of power, and this loss has been recently investigated by M. Emile Reynier, the well-known French electrician.

He considers, first, the case of an incandescent electric lamp, in which the resistance of the circuit is a constant quantity. The elements of the question are as follow:—

E_0 the initial electromotive force of the source.
R_0 resistance of the source.
E electromotive force of the secondary battery.
R resistance of the secondary battery.
E_1 difference of potential between the two extremities of the conductor mixed to incandescence.
R_1 resistance of this conductor.
t the time of the charge.
t_1 the time of the discharge.

The work, T_0, expended in charging will be

$$T_0 = E\,\frac{E_0 - E}{R_0 + R}\,t \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

The work, T, utilised in the incandescent conductor will be

$$T = \frac{E_1^2}{R + R_1}\,t_1 \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

To find the ratio of these two works, we must express t_1 as a function of t. This can be done by considering that the quantity of electricity, Q, is the same in the charging and discharging circuits, and that this quantity is proportional to the products of the intensities of the currents by the times; from whence is the equation

$$\frac{E_0 - E}{R_0 + R}\,t = Q = \frac{E_1}{R + R_1}\,t_1$$

and hence

$$t_1 = \frac{E_0 - E}{R_0 + R}\,\frac{R + R_1}{E_1}\,t \quad . \quad . \quad . \quad . \quad . \quad (3)$$

By substituting for t_1 its value in the expression (2), this becomes

$$T = \frac{E_1^2}{R + R_1}\,\frac{E_0 - E}{R_0 + R}\,\frac{R + R_1}{E_1}\,t = E\,\frac{E_0 - E}{R_0 + R}\,t \quad . \quad . \quad . \quad . \quad (4)$$

whence we get the yield of the battery

$$\phi = \frac{T}{T_0} = \frac{E}{E_0} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (5)$$

The efficiency is expressed, therefore, by the ratio between the difference of potential between the two ends of the resistance, which is incandescent, and the initial electromotive force of the electric source. It is independent of the resistances and the values of the times of charge and discharge.

In the foregoing investigation M. Reynier has supposed that the work was done by the discharge in the heating of a wire or conductor; but if the discharge current acts in a circuit which is itself the seat of an electromotive force—say, an electric motor—the expression for the efficiency is not altered. It is then incumbent, however, not to take for the value of E_1 the difference of potential at the two ends of the motor, because E_1 might to express the inverse electromotive force of the motor at the origin of the induction. We ought to arrive at the expression indirectly by putting

$$T_1 = Q\,E_1 \text{ and } T = Q\,E_1,$$

from which we get

$$\phi = \frac{T}{T_0} = \frac{E_1}{E_0} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (5)$$

These formulæ show how the resistances vanish from the final expression; they give us the relative and respective values of the times of charge and discharge, and show us that if the resistances do not act upon the final yield, they influence the time, and consequently the values, of the work expended and recuperated in unit time.

In practice, the resistances of the circuits ought to be taken into consideration. It is because of its very feeble internal resistance that the secondary battery of M. Faure gives a return of power or efficiency of 90 per cent. under advantageous conditions. In fact, the constants of the Faure battery are, for the small model of 7·5 kilogrammes,

$$E = 2{\cdot}15 \text{ volts},$$
$$R = 0{\cdot}006 \text{ ohm}.$$

Making $E_0 = E_1 + 1 = 3{\cdot}15$ volts,
$E_1 = E_0 - 1 = 2{\cdot}15$ volts,
$R_0 = R = 0{\cdot}006$ ohm,
$R_1 = R = 0{\cdot}006$ ohm.

The work expended during the charge will be

$$\frac{E_0^2}{2\,(R_0 + R)} = 4{\cdot}21 \text{ kilogrammes}$$

per second and per pair, a rule which admits of estimating the battery in time of charging much shorter than usual.

The work recuperated per second and per pair during the discharge will be equal to

$$\frac{E_1^2}{2\,(R + R_1)} = 2{\cdot}3 \text{ kilogrammes}.$$

As to the efficiency, it is, under these conditions, equal to

$$\frac{E_1}{E_0} = \frac{2{\cdot}3}{4{\cdot}21} \text{ or } 81 \text{ per cent}.$$

ELECTRIC RAILWAYS AND TRANSMISSION OF POWER BY ELECTRICITY.*

BY ALEXANDER SIEMENS.

When electricity was first utilised for practical purposes, the cost of producing it precluded its application to anything but giving signals or working small and delicate apparatus, requiring only weak currents to perform their functions; but by the discovery of the dynamo-electric principle, some fourteen years ago, powerful electric currents have been placed at our disposal, at a cost which enables us to transform into commercial processes a number of experiments which, up to that time, served only as illustrations of scientific lectures.

The machines which have caused this revolution in the application of electricity consist essentially of two parts—the fixed electro-magnets, by which a powerful magnetic field is created, and the revolving armature, which is connected with the commutator. When the machine is in action, the rapid motion of the armature through the magnetic field induces an electric current, which leaves the helix by the brushes pressing against the commutator on opposite sides. From the brushes the current passes to the electro-magnets, and afterwards to the outer circuit, where it has to perform the useful work. In traversing the coils of the electro-magnets, it increases the intensity of the magnetic field, which in its turn induces a more powerful current, and this mutual strengthening of current and magnetic field goes on until a balance establishes itself in the manner afterwards described.

The researches of Sir William Thomson, Dr. Hopkinson, Professor Ayrton, and others have proved that such machines, if properly constructed, will render in the form of electrical work up to 90 per cent. of the energy expended upon them in the form of motive power. It may, therefore, be conceded that they are very efficient transformers, and that we can hardly hope to exceed the results already obtained by the best types of dynamo-electric machines. If, instead of using such a machine to generate electricity you send a current into it, the magnetic attraction created between the poles of the electro-magnets and the armature tries to revolve the armature will cause the latter to rotate, and this motion can be communicated to other machinery in the usual ways. A pair of such machines, one for producing electricity and the second for retransforming the current into motive power, can, therefore, be utilised for transmitting power to a distance. In order fully to understand the manner in which this transmission is effected, a large number of experiments were made at the works of Messrs. Siemens and Halske, in Berlin, by Dr. Fröhlich, and the results obtained were laid before the Royal Academy of Science in Berlin by Dr. Werner Siemens on the 18th November, 1880.

The principal conclusions arrived at were the following:—In applying Ohm's law to a magneto-electric machine in motion with permanent magnets we find that the strength of current for a given total resistance is—

$$C = \frac{n \times M \times r}{R} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

In this formula C signifies the strength of current; n, the number of convolutions of wire on the armature; r, the number of revolutions per minute; R, the total resistance in circuit; M, the total E.M.F. produced by the permanent magnets and the iron of the armature in one convolution of wire, when $r = 1$; this quantity will afterwards be called "effective magnetism" of the machine.

The same formula holds good for a dynamo-electric machine. In this case, however, the "effective magnetism" M depends on the strength of current (C), and the formula, by substituting $f(C)$ for M, becomes—

$$C = \frac{r\,f(C)}{R} \text{ or } f(C) = \frac{C}{r}\,R \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

In the latter form the very important law is expressed that the strength of the current in a given dynamo-electric machine depends only on the ratio of the number of revolutions per minute to the total resistance in circuit. If we determine, therefore, f (C) for a machine, we can calculate beforehand the strength of current it will produce with a given number of revolutions in a given resistance.

The first series of experiments was made to test the correctness of this conclusion, and the curves I., II., and III., embody the results obtained by working one of the largest "Siemens" dynamo machine (type D_2) through various resistances at different speeds. The total resistance of the machine was, in case (I.), 0·68 S.U.; in case (II.), 7·25 S.U.; and, in case (III.), 7·74 S.U.

By way of comparison, the curve IV. was set out from results published by Messrs. Meyer and Auerbach in "Wiedemann's Annalen," Band 8, p. 491, who had experimented with a "Gramme" dynamo machine. As will be seen, all these curves do not differ materially from a straight line, and, for the limits of practical working, they fully confirm the above theory. There exists, therefore, a curious similarity between magneto-electric and dynamo-electric machines. In both, the strength of current is proportionate to the ratio of revolutions per minute to total resistance, although the magnetism of the magneto machines is a constant quantity, and that of the dynamo machine varies with the strength of current. The important difference between the two kinds of machine is, that magneto machines give a current however slow their motion is, whereas dynamo machines only begin to give a current when the ratio of number of revolutions to total resistance attains a certain magnitude.

The nature of the f (C) was then further examined, and the influence on the magnitude of the "effective magnetism" of the currents set up in the iron of the armature by its quick rotation in a magnetic field, and by the currents traversing the coils of the armature. The results arrived at are represented by the curves V., VI., VII., for the large Siemens machine, and by the curve VIII. for the Gramme machine referred to above. They show that at first the "effective magnetism" increases in proportion to the increase of current, then it deviates more and more until it very gradually reaches a maximum, and for still more powerful currents it decreases again. The latter peculiarity is to be accounted for by the fact that the iron bars of the electro-magnet cannot be magnetised beyond a certain point, whereas the diminishing influence of the currents on the magnetism in the iron of the armature increases continually with the strength of these currents. In practical applications such powerful currents are seldom met with, and it will suffice for the present purpose to assume that the "effective magnetism" gradually approaches a maximum.

When two machines, identical in their construction, are connected to transmit power, the "effective magnetism" in both should be equal, as the same current circulates through both of them. The following equations will, therefore, exist between the various quantities:—

$$E_1 = M\,r_1,$$
$$E_2 = M\,r_2,$$
$$C = \frac{E_1 - E_2}{R} = n\,M\,\frac{r_1 - r_2}{R},$$
$$W_1 = n \times E_1 \times C = n\,C\,R\,\frac{r_1}{r_1 - r_2},$$
$$W_2 = n \times E_2 \times C = n\,C\,R\,\frac{r_2}{r_1 - r_2},$$
$$H = n \times C \times R,$$
$$W_1 = H + W_2,$$
$$N = \frac{W_2}{W_1} = \frac{r_2}{r_1} = \frac{E_2}{E_1}.$$

In these formulæ the index 1 refers to the machine producing the current, and the index 2 to the machine giving out the power; E stands for electromotive force; n, M, r, R, C, signify the same quantities as before; n is a constant depending upon the construction of the machines; H is the heat, generated in the system; W_1 is the work expended upon the primary machine; W_2 is the work given out by the secondary machine; N is the useful effect.

In comparing these formulæ with observations, it is easily seen that they cannot be quite correct. This is most conspicuous with the formula for the useful effect, $N = \frac{r_2}{r_1}$, according to which this should be greatest the more the velocity of the second machine approaches the velocity of the first machine, whereas actual experiments show that N is a maximum for a certain velocity of the second machine, and will decrease for any greater or lower number of revolutions of the secondary machine. The cause of this discrepancy is the influence of the so-called Foucault's currents, which are set up in the iron of the revolving armatures by the proximity of the powerful electro-magnets.

In the primary machine these currents circulate in the same direction as the currents in the covering wire of the armature, weaken the "effective magnetism," increasing the work W_1 expended upon the primary machine. In the secondary machine, however, in which the armature runs in the opposite direction, these Foucault currents circulate in the opposite direction to the currents of the armature wires, and by thus strengthening the effective magnetism and the electromotive force E_2, they diminish the work W_2, given out by the secondary machine.

As our machines are supposed to be of identical construction, the following formula will express the relative proportion of the different quantities relating to the Foucault currents:—

$$M_1 = M - c\,r_1,$$
$$M_2 = M + c\,r_2,$$
$$c_1 = \frac{M_1 - u}{r_1} = \frac{1}{u} - \frac{E_1}{u\,r_1},$$
$$c_2 = \frac{M_2 - u}{r_2} = \frac{1}{u} - \frac{E_2}{u\,r_2}$$

M signifies the effective magnetism, such as it would be if no

The Storage of Electricity Accomplished.—Referring to the transmission of a hor, charged with electricity, from Paris to Glasgow, to which we recently alluded, Sir William Thomson, the eminent scientist, writes:—The "million of foot pounds" kept in the box during its 72 hours' journey from Paris to Glasgow was no exaggeration. One of the four cells, after being discharged, was recharged again by its own secondary battery, and then left to itself absolutely undisturbed for ten days. After that it yielded to me 240,000 foot pounds (or a little more than a quarter of a million). This not only confirms M. Reynier's measurements, but seems further to show that the wasteof the stored energy by time is not great, and that for days or weeks, at all events, it may be of practical moment. I have already ascertained enough regarding the Faure battery to make it quite certain that it solves the problem of storing electric energy in a manner and on a scale useful for many important practical applications. The largest useful application waiting just now for the Faure battery—and it is to be hoped that the very minimum of time will be allowed to pass till the battery is supplied for this application—is to do for the electric light what a water cistern in a house does for an intermittent water supply. A little battery of seven or eight Leaden reflects to give the incandescence in Swan or Edison lights to the extent of 100 candles for six hours, without any perceptible diminution of brilliancy. Thus, instead of needing a gas-engine or steam-engine to be kept going as long as the light is wanted, with the liability of the light failing at any moment through the slipping of a belt, the accident of no fireman, steam-raiser or engineer, breakdown or stoppage of the machinery, and instead of the waste of fuel inevitably during the hours of day or night when the light is not required, the engine may be kept going all day and charged at night, or it may be kept going day and night, which will undoubtedly be the most economical plan where the electric light comes into general enough use. The Faure accumulator, always kept charged from the engine by the house-supply when, with a proper automatic stop to check the supply when the accumulator is full, will be always ready at any hour of the day or night to give whatever light is required. Precisely the same advantages in respect of economy will be gained by the accumulator when the electric town supply is, as it surely will be before many years pass, regularly used for turning lathes and other machinery in workshops and sewing-machines in private houses.

Electric Vehicles in Paris.

On the 2d of June the application of electricity to locomotives by the system of M. Faure was experimented upon in the courtyard of the great Omnibus Company in Paris, where an omnibus was placed at the service of M. Hufford, the clever mechanical engineer of the Society La Force et la Lumiere. Nothing was changed in the vehicle; the apparatus was placed therein, and worked positively and without accident, the load struck at starting; notwithstanding the road was in bad condition and on a declivity. The experiments were equally satisfactory ascending or descending. In a few days the Company will have permission to run from Place du Trocadero to Passy by way of the Arc de Triomphe. It is thought these experiments will prove conclusively that the system of electric traction offers 20 per cent. economy, and no danger whatever even in crowded streets.

Times Gas Light Journ. July 2. 1881

The Storage of Electricity.

The London *Times* prints the following letter to the editor of that journal:

"SIR:—Although agreeing with every word of Sir William Thomson's letter in the *Times* of to-day, and entirely sympathizing with his enthusiasm as regards the marvellous box of electricity, still I feel that it would have been desirable if in pointing out the importance of this new discovery Sir William Thomson had guarded against a very probable misconstruction of the purport of his letter.

"The means of storing and re-storing mechanical energy form the aspiration of not only Sir William, but of every educated mechanic. It is, however, a question of degrees—of the amount of energy stored as compared with the weight of the reservoir, the standard of comparison being coal and corn. Looked at in this way, one cannot but ask whether, if this form of storage is to be the realization of our aspirations, it is not completely disappointing. Large numbers are apt to create a wrong impression until we inquire what is the unit. Eleven million foot-pounds of energy is what is stored in one pound of ordinary coal. So that in this box, weighing 75 pounds, there was just as much energy as in 1½ ounce of coal, which might have been brought from Paris or anywhere else in a waistcoat pocket, or have been sent by letter.

"When we come to the question of the actual conveyance of energy for mechanical purposes, this view is of fundamental importance. The weight of the same amount of energy in this new form is 800 times greater than the equivalent amount of coal; and as a matter of economy, supposing that energy in this form might be had at a certain spot and no capital were required for its conversion or storage, and that the energy were directly applicable, it could not be carried 10 miles—that is to say, such energy cannot be economically useful 10 miles from its source, although coal had to be carried 100 miles to the spot. Thus limit, in truth, fells far short of what has been already attained by other means. By wire ropes and by compressed air or steam energy may be economically transmitted from ten to twenty miles. So that if this is the utmost of what is to be done by means of the storage of electricity, this discovery adds another door to those which are hopelessly closed against the possibility of finding in Niagara or other water power a substitute for our coal, even when the object is motive power, and much more for that purpose for which free-stalks of our coal is used—the production of heat.

"It is very important that the people of this country should not shut their eyes to the fact that so far from there being a greater prospect of the solution of the problem than when, about twenty years ago, Professor Anyons raised the alarm, the prospect is now much smaller. In the meantime the capabilities of steel ropes, thinks in pipes, and electricity along conductors have been not only investigated, but practically tested and found altogether wanting. And now it would seem that the storage of electricity must be added to the list.

Effect of Electric Light on the Eyes.

An unexplained objection to the electric light arises from its alleged evil effects on the eyes. European observers state that the frequent variations in intensity to which the light is subject give rise to sudden and frequent changes in the pupil, and, consequently, in the "accommodation" of the eye, by which is meant that alternate contraction and dilation of the pupil, by which it suits itself to the variations of light. Such a light, therefore, causes not only muscular fatigue, but also a considerable degree of blurring and indistinctness in the retinal image. The eye suffers both when the light is too dim and when it is too bright. In the former case the object must be brought close to be clearly seen, and an increased accommodative effort is called for, which in most cases results in nearsightedness. In the latter case, the simple intensity of the light produces undue contraction of the pupil, and an increase of tension within the eye.—*Manufacturer and Builder.*

NEW-YORK DAILY TRIBUNE,

NOVEMBER 6, 1881.

In the House of Commons show that politicians of both parties stoutly resents the proposed new arrangements, and that there is a consensus of opinion against a conventional treaty, unless of a much more favourable nature than has as yet been set forth. It would be foolish to run the risk of retaliation on our part, yet we are afraid that a cry for that course of procedure may be raised unless our Commissioners wisely decline to assent to anything of a retrograde nature. To agree to the new duties upon cutlery and other handwares would be to virtually annihilate our trade in them with France, and, if that result is inevitably to follow, it had better be the outcome of the general tariff revision than is witnessed under a special arrangement, whereby which was got nothing and France everything.

THE STORAGE OF ELECTRICITY.

The storage of electricity, in the manner described by Sir William Thomson, whose letter we published, as regards its principal passages, last week, is of such transcendent importance that we need offer no excuse for again referring to the matter. Sir William Thomson, who is one of the highest living authorities, amply confirms the statement that a small box containing 1,000,000 foot-pounds of electric force has been conveyed from Paris to Glasgow. This small box was in reality a Faure secondary battery, in which the electricity can be accumulated and stored until it is regulated for use. By the application of the same kind of battery M Faure has run a bicycle, and has also applied the principle to a small boat which has been successfully tried over Paris. Sir William Thomson has tested this battery, and reports that it does really afford a means of storing electrical force —a fact which is of vital interest and importance to the public. As we have previously pointed out, the great defect of dynamically-created electricity has been its existence only so long as the motive-power was kept running. When the engine stopped the current ceased. Under the new plan this is no longer the case, and, as the eminent scientist named points out, the electric energy may be stored for household or other purposes, just in the same manner as water or gas. In this way we may light our houses, or utilize the electricity as power, under absolute control, and with a minimum of trouble and expense. Such being the case we may expect to witness an enormous development of the electric industry, accompanied, of course, that the Faure battery is capable of indefinite reproduction on a practical scale. There are not wanting those who would dispute the value of the invention, and who ridicule the ideas set forth by Sir William Thomson. Prof. Osborne Reynolds, of Owens College, Manchester, for instance, points out that, after all, 1,000,000 foot-pounds is a very small matter, being in fact just as small "energy" as is cohained in 1¼ oz. of coal. Coal, indeed, is to be our standard, according to Mr. Reynolds, and he predicts the utter failure of the plan for storing electricity. Professor Ayrton also comes forward as a critic, albeit one of a milder type, and admits the truth of the statement that 1¼ oz. of coal contains 1,000,000 foot-pounds of energy, but he very pertinently asks how that force is to be extracted to its full extent. As a matter of fact it is impossible to attain that result, so known engine being capable of working with no minute a quantity of fuel. This is exactly where the difference lies. The coal may contain the power, but it is all latent, and not available without the aid of a much greater force than its own, whereas the electricity is all immediately available, and can be used wholly or partially at will. Besides this the coal once used is done with, whereas the Faure accumulator can be stored anew, and drawn upon as required. This is an essential distinction,

---

The National Scientific Journal, Aug. 1st 1881. 33

THE STORAGE OF ELECTRIC ENERGY.—I am continuing my experiments on the Faure accumulator with every-day increasing interest. I find M. Reynier's statement, that a Faure accumulator, weighing seventy-five kilograms (165 pounds) can store and give out again energy to the extent of one hour's work of one-horse power (1,980,000 foot-pounds) amply confirmed. I have not yet succeeded in making the complete measurements necessary to say exactly what proportion of the energy used in the charging is lost in the process of charging and discharging. If the processes are pushed on too fast there is necessarily a great loss of energy, just as there is in driving a small steam-engine so fast that energy is wasted by "wire-drawing" of the steam through the steam pipes and ports. If the processes are carried on too slowly there is inevitably some loss through local action, the spongy lead becoming oxidized, and the peroxide losing some of its oxygen vicariously, that is to say, without doing the proper proportion of electric work in the circuit. I have seen enough, however, to make me feel very confident that in any mode of working the accumulator is not seriously slow, the loss from local action will be very small. I think it most probable that at rates of working which would be perfectly convenient for the ordinary use of fixed accumulators in connection with electric lighting and electric transmission of power for driving machinery, large and small, the loss of energy in charging the accumulator and taking out the charge again for use will be less than ten per cent. of the whole that is spent in charging the accumulator; but to attain such dynamical economy as this, prime cost in lead must not be aimed. I have quite ascertained that accumulators amounting in weight to three-quarters of a ton will suffice to work for six hours from one charge, doing work during the six hours at the uniform rate of one-horse power, and with very high economy. I think it probable that the economy will be as high that as much as ninety per cent. of the energy spent in the engine will be given out in efficient external to the accumulator. When, as in the proposed application to driving tramcars, economy of weight is very important, much less perfect economy of energy need be looked for. Thus, though an eighth of a ton of accumulators would work very economically for six hours at one-sixth of a horse-power, it would work much less economically for one hour at one horse-power; but not so uneconomically as to be practically fatal to the proposed use. It seems indeed very probable that a tramcar arranged to take in, say seventy-five kilograms (one-half hundred weight) of freshly-charged accumulators, on leaving head-quarters for an hour's run, may be driven more economically by the electric energy operating through a dynamo-electric machine than by horses. The question of economy between accumulators carried in the tramcar, as in M. Faure's proposal, and electricity transmitted by an insulated conductor, as in the electric railway at present being tried at Berlin by the Messrs. Siemens, is one that can only be practically settled by experience. In circumstances in which the insulated conductor can be laid, Messrs. Siemens' plan will undoubtedly be the most economical, as it will save the carriage of the weight of the accumulators. But there are many cases in which the insulated conductor is impracticable, and in which M. Faure's plan may prove useful. Whether it be the electric railway or the load-driven tramcar, there is one feature of peculiar scientific interest belonging to electro-dynamic propulsion of road carriages. Whatever work is done by gravity on the carriage going down hill will be laid up in store ready to resist sideroads in drawing the carriage up the hill, provided electric accumulators be used, whether at a fixed driving station or in the carriage itself.

WILLIAM THOMSON *in Nature.*

University, Glasgow, June 13.

The Faure Battery and Incandescent Electric Lighting.

The transmission of power to a distance from its generating point is a subject that has lately been much discussed in the leading newspapers, in consequence of Sir William Thomson's startling communication on the subject of the Faure battery, or "box of energy." It appears from the statements of the Glasgow professor that fifty Joule's equivalents of heat can be obtained at will from a box weighing 75 lbs. According to the figures, a box weighing 50 batteries will keep 20 incandescent electric lamps of 10 to 12 candle power each, in full action for six hours. These batteries will weigh altogether about 2200 lbs., or say 22s cwt., and will require only re-charging at the end of the second day. This, as already announced, will be shortly reduced to 1d., "or even less." Still, taken at the lower named figure, the batteries will cost 4s. 2d. per day for re-charging only. Carriage is not included, but if generating stations are established at intervals of a mile apart, a consumer situated midway between any of these stations will have to deliver and collect his batteries over a distance of at least a mile every day. This duty, with the necessary fixing and dismantling of the apparatus, exclusive of probable damage, will be cheaply done at 1s. 6d., so we have 5s. 6d. as the lowest daily cost of 200 lamps for battery power alone. These lamps are calculated to endure 500 hours' burning, so there would be a constant expense for their renewal even without accidents, which are very common to that style of lamp. Leaving this, however, with all capital charges, in illuminating power to gas at the common union or battwing tip burning under the most favourable circumstances imagined by the friends of the Faure battery of the future, not less than 5s. 6d. per 1000 six hours. An equal amount of light in the common gas-burners before mentioned would be obtainable with a consumption of 600 feet of gas—an average price of 1000 cubic feet, which at 3s. per 1000 an economy of 2s. 6d. for the six hours, as compared with incandescent lamps supplied with the Faure batteries. It should, however, be remembered that the English agent for this apparatus do not hold forth the immediate expectation of a less charge than 2½d. for re-charging a battery, so that for the present the cost of six hours' light, as above, from this source must be taken at 11s. 10d., or £30 of 50 batteries is £300.

Iron, Nov. 11th 1881.

Gas as a Motive Power.

Electricity as a Motive Power.—An interesting lecture has been delivered by Mr. W. Lanchin, C.E., on the "Secondary Battery." Successful results, he premised, had been obtained in lighting a train experimentally with electricity on the Brighton line. Referring to the electric Concorde, he stated that the increase in the Price of electricity in accumulators at a limited less cost per diem than horse-power, irrespective of the capital sunk in the purchase of horses at £40 each. He had worked a sewing machine from an electric accumulator, and he saw no reason why trains should not be run without any locomotive whatever. Mr. Appleyard, fully endorsing the remarks of the lecturer, expressed his opinion that the forthcoming electric exhibition in the Crystal Palace will far excel that held in Paris. Thanks were given to the lecturer for his very able paper. In response to said, he had already been prepared to prevent ignition in balloons.

English Mechanic & World of Science, August 19th 1881.

Nature, July 14th

Brush's Electric Storage Battery.—The

American *Electrician* announces that Mr. Brush has been a long time at work upon an improvement of electric storage, and that he has probably startle the public with a new Swan's lamp. The cells were charged in Paris by a Gramme machine, and were arranged in groups of four in cubical boxes, the whole being coupled up in series. The current supplied by this arrangement, shown by a galvanometer in the circuit while the lamps were alight, was almost twenty-three degrees, and was perfectly steady—the Faure battery yielding an almost equal current during the whole time, until the charge becomes exhausted, when it breaks down suddenly, without any noticeable warning. Mr. Spottiswoode also uses the Faure battery to work Swan

Mechanics' Mag. 7th 1881.

Storage of Electricity for Industrial and Home Use.—A new secondary battery, of greatly enlarged capacity, is now attracting attention in Paris. It is the invention of M. Faure, but is confessedly a development of the well-known secondary battery of M. Plantè, which is formed of sheets of lead immersed in acidulated water. The latter gains in capacity as the process of charging and discharging is repeated, though the resulting thickness of the layer of peroxide of lead that is slowly formed by the current is, M. Faure has conceived the idea of coating the two sets of plates with layers of minium, or the red oxide of lead, and by this means the capacity is greatly increased. The Faure battery is stated to be very lively down the power of accumulation of the Plantè. A battery weighing 75 kilogrammes will develop 75 kilogrammetres, or one horse power, during one hour. As to the nature of the action, the electric current, it appears to change the minium to peroxide on the positive electrode, and to reduced lead on the negative. In discharging, the reduced lead is oxidised, and the peroxidised lead is reduced. The battery was lately exhibited by M. Reyrner to the Society for Encouragement of National Industry. There were 24 couples weighing seven kilogrammes each; connected to a Siemens machine of medium size, they furnished a work of 25 kilogrammetres, which is about a third of M. Hyrtier's figures; but the conditions were unfavourable. Next, a battery of 24 couples, each weighing 12 millimetres thick, and 30 cms. square, separated by two strips of india-rubber, the whole being rolled up as shown in Fig. 1. The roll having been completed, the cylinder used in its formation is withdrawn, and it is consolidated by a wrapper of gutta-percha, and inserted in a glass jar filled with water and 1-10th part acid. An electric current is then made to pass through the cell; oxygen is given off, and produces a thick cushion of peroxide of lead on one sheet; hydrogen is given off at the other sheet. If the current with which the cell has been charged be cut off, and the two sheets are connected, a current will be produced, owing to the presence of the oxygen, which leaves the sheet where it has accumulated and attacks and oxidises the other sheet. This secondary current, which is very small at first, gains strength each time the operation is repeated; in course of time the surfaces of the sheets are changed, the one being covered reduced to a spongy mass. The cell is then complete, and is a state of electrical accumulation. That was the plan of separating the two sheets of lead by canvas, the cell taking the form of Fig. 2. He then found that it was necessary to leave a small space between the sheets to provide for the escape of the gases which were produced at the end of the charge; subsequently india-rubber bands were employed in preference to canvas. M. Faure also tried carbonate of lead, minium, &c., but without improving upon the results already obtained. The

Fig. 1.

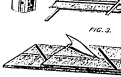

Fig. 2.

Plantè and Faure Batteries.

In annexed illustrations of the secondary batteries, which are exciting so much interest at the present time in, with the accompanying description, enable the reader to understand their construction. At the recent meeting of the King's College, several forms of electric-lighting apparatus were used; but that which attracted most attention was a battery of forty-four accumulators of Faure's design, working twenty of Swan's lamps. The cells were charged in Paris by a Gramme machine, and were arranged in groups of four in cubical boxes, the whole being coupled up in series. The current supplied by this arrangement, shown by a galvanometer in the circuit while the lamps were alight, was almost twenty-three degrees, and was perfectly steady—the Faure battery yielding an almost equal current during the whole time, until the charge becomes exhausted, when it breaks down suddenly, without any noticeable warning. Mr. Spottiswoode also uses the Faure battery to work Swan

Fig. 1.

and Maxim Lamps in his private house. Figs. 1 and 2 show sheets of lead (it may be as thin as stout lead-foil) are laid together, with the other, separated by two strips of india-rubber; the whole being rolled up as shown in Fig. 1. The roll having been completed, the cylinder used in its formation is withdrawn, and it is consolidated by a wrapper of gutta-percha, and inserted in a glass jar filled with water and 1-10th part acid. An electric current is then made to pass through the cell; oxygen is given off, and produces a thick cushion of peroxide of lead on one sheet; hydrogen is given off at the other sheet. If the current with which the cell has been charged be cut off, and the two sheets are connected, a current will be produced, owing to the presence of the oxygen, which leaves the sheet where it has accumulated and attacks and oxidises the other sheet. This secondary current, which is very small at first, gains strength each time the operation is repeated; in course of time the surfaces of the sheets are changed, the one being covered reduced to a spongy mass. The cell is then complete, and is a state of electrical accumulation. That was the plan of separating the two sheets of lead by canvas, the cell taking the form of Fig. 2. He then found that it was necessary to leave a small space between the sheets to provide for the escape of the gases which were produced at the end of the charge; subsequently india-rubber bands were employed in preference to canvas. M. Faure also tried carbonate of lead, minium, &c., but without improving upon the results already obtained. The

has been lately started in Paris by M. Philippart, for obtaining force and light from electricity, the combination of Faure and Faure batteries. M. Hospitalier has pointed out the expensiveness of charging the Faure battery with electricity from ordinary motive.

Mining & Scientific Press June 25, 1881.

Storage of Electricity.

A Wonderful Alleged Discovery.

A correspondent of the London *Times* makes an announcement which, if fully borne out by the facts, is of the highest possible importance. He states that M. Camille Faure, a noted French scientist, has discovered a practical means of storing electricity and rendering it portable. It is almost unnecessary to remark that nothing of the kind has been possible hitherto, and that it has been regarded as being impossible to store up electric energy in a portable condition. At a recent public session of the Academy of Sciences another Frenchman, presided over by the president of the French Academy of Science and surrounded by many leading English scientists, the secret of the discovery is said to have been demonstrated, and the possibility of a doubt. A Faure battery was charged with the electric fluid direct from the ordinary Grove battery. The receptacle con-

Digitized by Google

sisted of four Faure batteries, each about five inches diameter and 10 inches high, forming a cylindrical leaden vessel, and containing alternate sheets of metallic lead and minimum wrapped in felt and rolled into a spiral wetted with acidulated water, and the whole placed in a square wooden box, measuring about 1 cubic foot and weighing about 70 lbs. This was protected by a loose wooden cover, through which the electrodes (in lead) protruded, and were fastened down for convenience of transport. This box was handed to the writer of the letter in question, who left Paris on Tuesday night, arrived in London on Wednesday, and finally reached Glasgow, where the box was presented to Sir William Thomson.

That eminent man is now experimenting with the box in the laboratory of the Glasgow University, and will no doubt give the world the benefit of the results of his tests at an early date. Were the matter rests at present, but if all this be true there is no doubt that we are on the eve of changes which will completely revolutionize many of our existing appliances and processes, especially as regards lighting and heating. This small box, measuring about one cu. ft., is said to contain a power equivalent to nearly 1,000,000 foot-pounds—a force, of which we can only speak comparatively, and without adequate knowledge of the resources of the plan on a larger scale. It is plain, however, that if electricity really could be stored and then conveyed from place to place we might look upon the future of illumination, by that means, as being thoroughly and completely assured.

At present the great drawback lies in the circumstance that the generation of the electric force and the production of the light are quite simultaneous. When the machine stops, the light disappears, and stops at once. If, then, means be devised to intercept and store up a portion of the whole of this force for subsequent use, the difficulty would disappear, and electricity will take rank as a handy, manageable and economical means of illumination. The mere supposition opens out a vista which cannot be accurately thought out or described, seeing that, for domestic, railway, mining, manufacturing and scientific purposes, the electric current would indubitably replace gas and all other illuminating media. Before counting these as accomplished facts, however, many economical and other points must be satisfactorily explained. The outcome of Sir Wm. Thomson's investigations will be awaited, therefore, with more than ordinary interest.—*Ironmonger, May 21st.*

Later Advices.

A London special to the New York *Times* of June 7th, and written nearly three weeks after Mr. Thompson's arrival, was first cabled to the outer, says:—The latest advantage of electricity by the use of the Faure battery has attracted the universal attention of the scientific men of Europe. As has been previously stated, William Thompson, the eminent scientist of Glasgow, lately took from Paris to Glasgow a box used to store and transport the electric power. He has already ascertained enough regarding the capacity of the Faure cells to make it quite certain that it solves the problem of storing electric energy in a manner and upon a scale to render it useful in many important practical applications. Among others, enough can be stored to give light in a house for several hours without an additional supply. The reservoir can be moved easily and used where the dynamo-electric machines are unavailable. One great advantage to be found is in the fact that when the energy is supplied from a Faure reservoir it is always steady in delivery, thus preventing fitful oscillations in the light, experienced from the unequal action of the ordinary dynamo machines.

American Omnister, May 1881.

Portable Electricity.

By the wonderful invention of M. Camille Faure, of Paris, there is compressed within a portable package of one cubic foot an electric energy equal to a million feet. This package consists of four Faure batteries, each about five inches in diameter and ten inches high, forming a cylindrical leaden vessel, and containing alternate sheets of metallic lead and minimum, wrapped in felt and rolled into spirals, wetted with acidulated water, the whole placed in a square wooden box measuring about one cubic foot, and weighing about seventy-five pounds. It is protected by a loose wooden cover, through which the electrodes in lead protrude. One of these packages was recently sent from Paris to Sir William Thomson, at the Glasgow University. After some severe tests and experiments, Sir William exclaimed, "Why, it is a little giant."

It would seem most probable that the advantages to science and humanity from this wonderful discovery must be of the most transcendent importance.

Nature, June 30th, 1881.

Storage of Energy

Like many others, I have given much thought to the accumulation of force, and have felt much astonished at the account of Faure's battery, if it is to be a cyclet, although of course such a development was to be expected from the time that Plante made his.

I see that men immediately rush to waterfalls, rivers, and tides to obtain the power for accumulation when they leave coal and wood; my ideas are rather in the direction of wind; and I have often thought our country favored, like that around Zanzibar, with windmills. The wind is not constant, but more so than many of our efficient streams, and it is found at every spot. The power is quite unlimited, and we can moderate the action of the machine by increasing or closing the respective forces. Storage batteries have been required. I have imagined our windmills pumping up water to reservoirs, but we have not yet learned to make reservoirs for water except at an enormous expense and in unexpected valleys (after imagining we have come into many mind), but if we have really true and safe storage, such as described, the wind will become our fire to warm us, our steam to drive us, our gas to light us, and our universal servant. The wind will drive our mills, it will pump when a fog comes, lasting so long that our stores of power fail, with sufficient storage, inconstancy will cease to trouble us, because every valley may have its Niagara and every mountain top its beacon, and darkness will scarcely trouble mankind in the next great world of light. We have heard of the golden servants of Vulcan, and the mechanical slaves of the great Khan. What will be the power which when every mill has its dynamo, by a command can set the lightning at its service by friction, like Aladdin? It seems to me that the wind is the great power that we shall next use, and that France—the power of the air—shall be bound to serve us for at least a thousand years.

The Dutch have long made windmills, but when ever in Holland a few years ago examining a little, I was unable to find the books wanted on the subject.

The fact that our mills be carried will not affect the question if wind is a cel. Wind carries itself. We shall seek our power from the breezes instead of the inferred pile, and a race of healthy, ruddy faces will take the place of the blackened and ill-fed countenances from mines.

I wish to show that we have oceans of power in the wind. Will this storage accumulator, of which I know nothing from personal experience, serve us to keep it for hours and days from a great period. Coal becomes necessary if we accumulate the force of the wind, and Niagara itself will be no longer wanted. Of course we need machines to use the wind-power. At present coals are cheaper with us, but so in all parts of Holland, and enough to solve; do not let us throw cold water on the discoveries of others, or show, as scientific men so often do, our own opinion to be deep beyond the truth among others.

R. A. S.

The Ironmonger, May 21st, 1881.

STORAGE OF ELECTRICITY.

An anonymous correspondent of the *Times*, signing himself "P.E.R.S.," makes an announcement which, if fully borne out by the facts, is of the highest possible importance. He states that M. Camille Faure, a noted French chemist, has discovered a practical means of storing electricity and rendering it portable. It is almost unnecessary to remark that nothing of the kind has been possible hitherto, and that it has been regarded as being impossible to store up electric energy in a practical manner. At a recent public séance of the Société d'Encouragement pour l'Industrie, presided over by the president of the French Academy of Science and attended by many leading English scientists, the success of the discovery is said to have been demonstrated beyond the possibility of doubt. On Monday last, we are told, in Paris, a Faure battery, *or pile secondaire*, was charged with the electric fluid direct from the ordinary Grove battery. The Grove battery, it may be remarked, is a powerful generator of electricity, but it was explained that frictional electricity might have been applied by means of a Gramme or Siemens machine. The receptacle consisted of four Faure batteries, each about 5 inches diameter and 10 inches high, forming a cylindrical leaden vessel, and containing alternate sheets of metallic lead and minium wrapped in felt and rolled into a spiral wetted with acidulated water, and the whole placed in a square wooden box, measuring about 1 cubic foot and weighing some 75 lbs. This was protected by a loose wooden cover, through which the electrodes (in lead) protruded, and were fastened down for convenience of transport. This box was handed to the writer of the letter in question, who left Paris on Tuesday night, arrived in London on Wednesday, and finally reached Glasgow, where the box was presented to Sir William Thomson. That eminent man is now experimenting with the box in the laboratory of the Glasgow University, and will no doubt give the world the benefit of the results of his tests at an early date. There the matter rests at present, but if all this be true there is no doubt that we are on the eve of changes which will completely revolutionize many of our existing appliances and processes, especially as regards lighting and heating. This small box, measuring about 1 cubic foot, is said to contain a power equivalent to nearly 1,000,000 foot-pounds—a force of which we can only speak comparatively and without adequate knowledge of the resources of the plan on a large scale. It is plain, however, that if electricity really could be stored and safely conveyed from place to place we might look upon the future of illumination, by that means, as being thoroughly and completely assured. At present the great drawback lies in the circumstance that the generation of the electric force and the production of the light are quite simultaneous. When the machine stops, the light disappears, and stops at once. If, then, means be devised to intercept and store up a portion of the whole of this force for subsequent use, the difficulty would disappear, and electricity will take rank as a handy, manageable, and economical means of illumination. The mere supposition opens out a vista which cannot be accurately thought out or described, seeing that, for domestic, railway, mining, manufacturing and scientific purposes, the electric current would indubitably replace gas and all other illuminating media. Before counting these as accomplished facts, however, many economical and other points must be satisfactorily explained. The outcome of Sir Wm. Thompson's investigations will be awaited, therefore, with more than ordinary interest.—*Ironmonger, May 21st.*

The Electrician, July 9th, 1881.

STORAGE OF ELECTRICITY.—In our issue of June 18, on page 18, we referred to a letter of Major Scarse to *The Times*. We give herewith the letter and the preliminary comment as it appeared in our daily contemporary :—

"The following letter refers to our recent remarks on a new company called 'La Force et la Lumière.' The explanation while it proves the necessity for our remarks, appears to be fully satisfactory as far as the writer of the letter and Sir William Thomson are concerned :—' Paris, June 14. Sir:—As a director of the 'Société La Force et la Lumière' you have rendered me a great service by your remarks in the *City* article of *The Times* of yesterday. Permit me to thank you for it and to point out that the shares are now being offered to the public are not, properly speaking, an issue by the company, but simply a sale by a private individual, who received them in part payment for the transfer of patent and other rights to the company. You are quite right and justified in explaining that Sir William Thomson is not in any way identified with the financial operations of the company, and I trust you will allow me also to explain my connection with it, which to a great extent is merely the same. I think I am entitled to this, as my letter, printed in *The Times* on the 19th of May last (under my initials and before I was connected with the company) was the first explicit public announcement of the great things to be expected by storing electric energy. Like Sir William Thomson—but in an infinitesimal degree comparatively—I am a man of science and not a financier, and my attention having been drawn to the novelty of M. Faure's discovery, I went into the matter on my *answer*, with the intention of bringing it before Sir William, and discovery of the importance of which you have formed no meagre or erroneous estimate in your leading article of the 20th inst. It was to my friend Sir William Thomson, as a friend and colleague, against any undue use of his name or position as consulting engineer to the company that I consented to accept a seat on the board, and on the express condition that no prospectus or publication of any sort bearing his name should be issued without his previous approval and consent. Unfortunately, I was absent from Paris for over three weeks, and it was only at Vienna, when too late to stop the issue, I learnt that the prospectus you refer to had been put into circulation. I could only telegraph the fact to Sir W. Thomson, offering to withdraw from the company in case he disapproved the contents of the circular. I never saw it until my arrival here a few days ago, and I am, I regret to say, full of misgivings, if necessary, how annoyed and dissatisfied I was at the proceeding. I have only to add and repeat that the prospectus you refer to is not an issue by the company, but a sale of shares for private account; and while I am quite convinced of their value and the great future open to us in the electrical world, I wish it to be distinctly understood from me, as the only Englishman on the Board, that the operations of the parent company 'La Force et la Lumière' in England are to be confined to the transfer of their patent and other rights to an exclusively English company with a board of directors of the highest standing in the electric and financial circles of London, and that the entire control of its future operations will rest in the hands of gentlemen whose names will be a guarantee against a shadow of suspicion.—Yours, &c., F. J. Rebards-Shavery."

IMPROVED ELECTRIC GENERATOR.

A great deal of attention is now given to the relief and cure of diseases without the use of drugs, and electricity is being recognized as one of the important healing agents for accomplishing this very desirable end. Hitherto it has generally been considered the prerogative of a physician to properly apply the electric current to curative purposes; but since it has been discovered that a mild continuous current is effective in the treatment of diseases, it is apparent that any one having the necessary appliances may use the electric current to advantage.

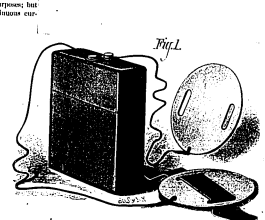
The engraving represents a very simple and compact generator or battery for creating a continuous electric current for curative purposes. It is a modification of the well known Trouvé bluebing paper battery, and is capable of yielding a constant current for a long time.

The inventors of this generator and its accessories state that they have batteries of this class in use yielding a current for over a year without attention, and it may be renewed at the end of that time without trouble or expense.

The rubber case contains two plates, one of zinc, the other of copper, each connected with a clamping screw extending through the cover. Flexible cords connect the binding posts with the electrodes, the latter consisting of two nickel plated disks, each having two slots for receiving a strap by which the electrode may be bound upon the affected part. The generator is carried in a pocket in the inside of one of the garments. This may be done with perfect safety, as the exciting fluid with which the generator is charged is entirely absorbed by the porous filling placed between the zinc and copper plates.

The electrodes are often worn on a belt, one being placed in front of the body, the other at the back. Fig. 2 shows the method of attaching one of the electrodes to a sponge for bathing purposes, and Fig. 3 shows its application to the head when the current is employed to supplement frictional treatment.

There are a number of other methods of applying the current, which need not be described in detail here. Further information in regard to this invention may be obtained by addressing the Constant Current Corporation, 203 Main street, Buffalo, N. Y.



CONSTANT CURRENT ELECTRIC GENERATOR.

Nature, July 21, 1887.

OUR Paris correspondent informs us that Philippart and Sons are preparing to work tramways at Roubaix with improved Faure batteries, and that experiments will also shortly be made in London. Our correspondent adduced some preliminary experiments which he thinks give room for high expectations. One of the most important changes is the substitution of flat for coiled sheets, which produced numerous cracks in the oxidized coating, and had been resorted to in imitation of the old Planté batteries.

Journal of Gas Lighting, &c. Aug. 1887.

THE FAURE BATTERY SCHEME.

THERE is at present an attempt being made to force the Faure secondary electric batteries on the British public, as the foundation for a joint-stock enterprise. To this end a shop has been taken in the Strand, London, where a show is made of some kind of incandescent electric lamps, ostensibly maintained in action by the appliances which Sir W. Thomson is said to have called a "witch," when he first became aware of its peculiarities. Circulars setting forth the advantages of the Faure batteries are being freely distributed, making it appear that sewing-machines, vehicles, boats, and electric lamps can be worked by stored electric energy at a great economy in comparison with existing sources of power. How far these claims are justified in the single matter of electric lighting by incandescence, a "Note" in the present number of the JOURNAL will be found to show. The notice taken in another column of these pretensions might be considered a sufficient exposure of their hollowness; but in the interest of the investing public we here repeat that, according to their own showing, the agents of M. Faure cannot promise any one who may be disposed to sink at least £250 in batteries and lamps, a light at less than something like four and a half times the cost of gas in London. This circumstance is absolutely conclusive as to the chances of the Faure battery superseding any tolerably effective system in which the current is produced from the generators; to say nothing of its pretensions in a competition in which even those latter have failed. It is foreign to our sphere to investigate the claims of the secondary battery for other purposes than lighting, but it sounds strange to hear of four cells, weighing together 200 lbs., being only able to propel a tricycle for six hours. This is scarcely man-power, and unless a very great improvement can be effected somewhere, the apparatus will never supersede a single donkey-engine. The improvement may, of course, be realized in time; but meanwhile the public will probably be chary of embarking capital in support of apparatus which is in its right place only in the experimental laboratory of Sir W. Thomson, or somebody else.

ELECTRICAL STORAGE OF DYNAMIC ENERGY, AND THE KENNEDY SYSTEM OF ELECTRIC LIGHTING.

[10677.—On June 10 last a letter appeared in a contemporary written by me, and likewise expressing my views concerning certain notes of the uses and applications of the storage battery, &c.

I will here quote a portion of that letter where I say that "The storage of electricity is the only means by which a uniform current can be obtained for electric lighting, &c. It will be to the electric lamp what a steam-boiler is to the steam-engine. Dynamos, like steam-engines, are irregularity of the speed of the motor that drives it, whether it be in the slip of the driving belt or other causes, variations in the current will occur."

"This difficulty may be overcome entirely by using storage batteries, whether of Faure's or any other equally adapted; and so long as two of these reservoirs are kept supplied by the dynamo machine, one being charged while the other is being used, the battery so automatic action in this supply when the reservoirs are full, and to cut off when they require replenishing, will result, if not entirely at, the defects and objection in electric-lighting being done away with.

"I have set up as patent for this prediction and application, but as regards storage batteries I find many objections to their use, although there are very many ways in which they can and will be used, but the general and most important is their application to electric lighting and motive power. Small, as well as large, electric-motors are now being made expressly to be used with the storage batteries, and will very soon be common on the market. I have used with good effect a storage battery with my motor, but have not been able to obtain one so cheap and efficient as with M. Faure's battery. I fully see a great boon, and efficient as it is, it is only fit for use in a motor, and another yet to come, more potent, and of small weight." &c.

I believe that I am quite right in describing this system, and I am sure that Mr. Kennedy, like myself, is less an appreciation of the uses of storage batteries.

His letter (10633) of Aug. 5 is indeed a repetition in words, and exemplified in works, of what I have previously described in the 10th of June. I can gratulate him for the step he has taken; but at the same time I must say with every respect, remind him that others have been, and others are doing, what he is stated to have done, and what he claims as his exclusive system of electric lighting. There are some things that I could also claim as their system of electric lighting, but I would be the last object of presumption to claim as such. All that I can do, he can do, or others can do, and I make it known that the system of lighting adopted by him, or them, is from the use of storage batteries.—EDS.]

Mr. Kennedy says that the dynamo-electric machines employed would not produce the effect whatever, apart from the accumulators. No doubt the electromotive force of such as he uses is very low; it is, however, quite an easy to change a series of accumulators, as one only, if a dynamo be used having a small greater electromotive force, and with its armature insulated accordingly. Our esteemed friend, Mr. Kennedy, in his letter 4337, there will be local action and great loss of charge unless other people get better results than he has. It is quite true, and the reason is, I think, because the accumulators had not been long enough used. I have found there is great local action at first, which I find gradually lessens as they are used, and after repeated charges and discharges, the local action is very slight indeed, and almost this local action can be overcome. What next? A. The game.

THOMAS SLATER.

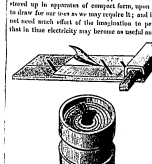
Westbourne Park, W., August 1.

The Faure Secondary Battery.

In a previous issue of this *Journal*, we alluded at some length to the interesting results obtained with the Faure secondary battery in rendering possible the storage of electrical energy in considerable quantity, and its preservation in potential form, without serious waste of energy, for a considerable time, and after the apparatus in which it had been accumulated had been transported from place to place. The possibilities which this interesting result opens, in respect to placing at our disposal electrical energy in some available and serviceable form, have awakened decided interest throughout the scientific world. The hope is certainly warranted that in the near future we shall have at command abundant supplies of electricity stored up in apparatus of compact form, upon which to draw for our uses as we may require it; and it does not need much effort of the imagination to perceive that in time electricity may become as useful and valuable in the Patent. The roll is then placed in a cylindrical lead cell, the outside of which is strengthened with copper bands and the inside covered with red lead and leather, so as to increase the useful surface of the battery. The latter then presents the appearance shown in the sketch, and one of the projecting wires from the lead plates is bent over and soldered to the enclosing cylinder, which is ready for use when it has been filled with water and about 10 per cent of sulphuric acid. The apparatus when charged weighs about 20 pounds. It will be seen that this differs from the Planté secondary battery only in the employment of red lead. The material chiefly employed is the same, the mode of construction is similar, the leather taking the part of the cloth previously used by M. Planté; it has no merit in itself; on the contrary, it is a cause of resistance, and is liable to deterioration, being useful only to keep the red lead in place. It is, in fact, this red lead which constitutes the new feature and gives the special advantage to the apparatus.



The Faure Battery.

veyed a current among civilized people at steam, though it must be confessed that much remains to be accomplished before this state of affairs is reached.

We give in the following a description, with an illustration of the Faure secondary battery, with which the interesting results reported by Sir William Thomson were obtained. The description is abstracted from an ably written article by M. Giraldy in a recent number of *Le Journal Universel d'Electricité*, criticising the comparative merits of the Planté and Faure batteries. The Faure secondary battery is protected by two patents, dated October 20, 1880, and February 9, 1881, respectively. In these patents M. Faure describes principally those batteries composed of lead plates laid on frames covered with red lead, and protected by leather, attached by flexible lead rivets, an arrangement similar to the rectangular batteries of M. Planté. The actual batteries are not so made, being constructed as follows: Two sheets of lead are taken, 7.87 inches wide; one of these plates is 23.62 inches long and 0.31 of an inch thick; the other is 15.75 inches long and 0.02 of an inch thick. Each plate is covered on both faces with a layer of red lead reduced to a paste by water, 1.76 pounds being spread over the larger plate, and 1.54 pounds over the smaller. On each face thus prepared a sheet of parchment paper is placed, and the whole is introduced into a sheath of thin leather. One plate is then put on top of the other and rolled up, strips of rubber being interposed obliquely, as shown

The roll is then placed in a cylindrical lead cell, the outside of which is strengthened with copper bands and the inside covered with red lead and leather, so as to increase the useful surface of the battery. The latter then presents the appearance shown in the sketch, and one of the projecting wires from the lead plates is bent over and soldered to the enclosing cylinder, which is ready for use when it has been filled with water and about 10 per cent of sulphuric acid. The apparatus when charged weighs about 20 pounds. It will be seen that this differs from the Planté secondary battery only in the employment of red lead. The material chiefly employed is the same, the mode of construction is similar, the leather taking the part of the cloth previously used by M. Planté; it has no merit in itself; on the contrary, it is a cause of resistance, and is liable to deterioration, being useful only to keep the red lead in place. It is, in fact, this red lead which constitutes the new feature and gives the special advantage to the apparatus.

According to the inventor, there are two advantages gained. The long and delicate operation necessary to prepare the Planté battery is not required. (This operation consists in passing through the battery an electric current, when oxygen goes to one plate and produces a thin coat of peroxide of lead, and hydrogen goes to the other plate). The second advantage claimed is that the battery has a storage capacity much greater than that of Planté, the proportion, according to M. Reyster, being, as deduced from numerous experiments, forty times greater with equal weights of batteries.

The article from which we glean the above description, then proceeds to criticise the relative merits of the Planté and Faure batteries, a subject with which in this place we are not specially interested.

Captain Richmond's Model Steam
May 13, 1871.

STORAGE OF ELECTRICITY.

A NEW secondary battery, of greatly enlarged capacity, is now occupying attention in Paris. It is the invention of M. Faure, but is confessedly a development of the well-known secondary battery of M. Planté, which is formed of sheets of lead immersed in acidulated water. The latter gains in capacity as the process of charging and discharging is repeated, through increasing thickness of the layer of peroxide of lead that is slowly formed by the current. M. Faure has conceived the idea of using, instead of solid sheets of lead, a mixture, or thin red oxide of lead, and by this means the capacity is greatly increased. The Faure battery is stated to have forty times the power of accumulation of the Planté. A battery weighing 70 kilogrammes will develop 75 kilogrammetres, or one horse-power, during one hour. As to the nature of the work which can be performed by discharging the current generated on this battery, electrotyping, and to reduce lead salts negative. In decomposing the reduced lead is oxidized, and the peroxidized lead is reduced. The battery was lately exhibited by M. Reyster to the Society for encouragement of national industry. There were 21 couples weighing 100 kilogrammes each; connected to a Siemens machine of medium size, these furnished a work of 17 kilogrammetres, or 1.7 horse-power, as M. Reyster's figures; but the process was unfavorable. Next, a band of platinum, 1 millimetre long, 2 millimetres broad, and 1-30th of a millimetre thick was made to glow; then two inches of platinum wire were fused. The superiority to the Planté battery was well demonstrated. Some competent physicists present thought that Faure's battery as a means of distributing electricity to any house or workshop, independently of gas, that may be applied, and from the experiments of a system of installation. The method is also applicable to generating for domestic electric lighting. A current may be added, has been lately started in Paris at 5 francs per hour, including force and light for electricity, for the decoration of the Opéra and Faure batteries. M. Hospitalier has criticised the expensiveness of charging the

view of its many elevating influences, could almost be termed a blessing? To this we answer, "Yes." What we at first require is an acknowledgment from the educated portion of our community that music has a value beyond the mere charm of an accomplishment; that it should be a part of a man's education as much as Latin or geometry.

In all our schools we should have music taught in a thorough and systematic manner. To many it might be an uninteresting study, but to few a useless one; for if they did not in after years continue the actual practice of music, there might still be a possibility of retaining that appreciation of its value which would lead their children to cultivate what they themselves had neglected.

This might be a slow process by which to raise and to create musical standards, but who could doubt of its being a sure one? We cannot sensibly make a musical nation by symphony concerts, regimental bands, and great musical festivals.

At present music is looked upon as such an entirely unnecessary accomplishment that our private schools give it little attention, and allow no extra time to such of their pupils as undertake the study. The consequences is, parents are unwilling to impose upon their often overtasked boys a study which for some years must necessarily be tiresome, and to most children uninteresting. The frequently-adopted plan of waiting to see whether children "have any taste" or "show any love" for music, is a wrong one. No child would prefer practicing scales to playing ball; and few boys, if the cultivation of their tastes depended upon the whims of their ever-flying fancies, would turn them into educated men. They give them the opportunity of forming a taste, and for its development trust to the esthetic element of their nature.

Admitting that music is taught to the best advantage in private lessons only, for by that method the pupil obtains that which is most required—the personal attention of the teacher—it still may be taught to the masses, in schools successfully, but only in a general way. A member of one of our Educational Boards once remarked that "in the musical education of the masses, precepts, maxims, laws of general application, a good taste, methods and habits of study and of practice, and the general principles of the art are mainly to be inculcated." This is, indeed, the case, for in class training it will only be the general powers that are developed, while the thousand and one little peculiarities and traits which indicate an individual capacity and talent will, necessarily, not be seen. In the earliest attempts to develop the minds of children, the musical training should be commenced. There should not only be the ability to *read* well, but to *sing* well. *The power to read musical instruction should begin in in the primary schools.* Numberless foreign examples are constantly before us; for instance, in Germany, known to be the most musical country in the world, vocal music is taught as thoroughly as the alphabet. In most of our cities, vocal music enters considerably into the curriculum of primary instruction; but efficient instruction is but too seldom met with. Vocal music in the school-room has a singularly tranquillizing influence upon the hearts and minds of the children. In Germany there is not a school that does not afford excellent and abundant material for chorusses; and there is no reason why it should not be so with us. Our chief fault is that we allow musical instruction to commence too late in life. Children, with ordinary talent, can very easily learn at six or seven years of age and thus lay the foundation for future excellence. The rudiments of music are readily comprehended by children; and the art of chaining is as attractive to them as the most melodious vocal exercises. Indeed every lesson proves that music has a wonderful power to amuse. Nearly every home boasts of its piano, or some simpler instrument, and it is an undeniable, irrefutable fact, that for these instruments, many whose leisure hours would be spent in disreputable society, or in wretched dissipation, are attracted to that place so dear to all genuine American hearts,—home.

It is unfortunate that so many trashy songs and instrumental pieces hold a prominent place upon the music-stands of most households; but it will not, until public appreciation is raised to a higher standard, cease to be thus. We may be assured that in the future—the early future it is to be hoped—we shall find the very best music a common source of enjoyment in each and every household. There are many unmistakable guide from the mere performance of music. For example: to read the biography of some composer, an analysis of some of his works, and then to hear them performed, alone would be the means of arousing the healthy minds, an interest that would seldom fail to bear good fruit. In addition all that we have predicted and hope for, ever come to pass, would there ever be a want of voices in church choirs, or choruses for oratorios or opera.

The principles we have endeavored to inculcate here, and to impress upon the reader, once recognized, as they are to a very great extent on the Continent of Europe to-day, would, ere many years, insure to music an important place in the education and estimation of every American. Then, and not till then, shall we feel in their full power, those refining and civilizing influences which music, like all beautiful arts, brings to those who award her the place which her votaries hope and believe she will yet hold in the New World as she now does in the Old.

THE STORAGE OF ELECTRICITY.

BY CHARLES MORRIS.

A DISCOVERY, which may prove of considerable future importance, has been lately announced in the English scientific journals, and has been sufficiently detailed in the newspapers to need, perhaps, no further comment, except for the correction of possible false conceptions concerning it. We refer to what has been entitled "The Storage of Electricity." Since scientists, as well as less learned writers, speak of it under this title, and since such a title is apt to give a wrong conception of what the discovery really embraces, it may be well to present a more definite description of the true principle involved, and thus to correct the false idea conveyed by the above phrase.

Electricity cannot be stored, any more than heat can be stored. Not as much, in fact, for heat is slow in its movements, and a stock of it can be made gradually to yield its energy; but electricity is instantaneous in its transfer, and only by its continued reproduction can a continued effect be gained from it. All that is really meant by the misleading phrase, "the storage of electricity," is the preservation of conditions for the spontaneous production of electricity. In fact, there is no discovery here of any scientific principle, as the announcement might indicate, but merely of an application of a principle known almost as long as electricity itself.

In every galvanic battery electricity is stored, in the same sense as in this new arrangement. It is simply a new form of galvanic battery, its only advantage being the peculiar form in which the requisite chemical conditions are produced, its portability, and its electrical power.

To understand this more clearly, it may be well to present a general review of the physical principle concerned in all manifestations of force. We may first consider water as the flow of force down hill, to seek its level below. It is only during this downward flow that available energy is set free, and that work is performed. A weight suspended above the earth is capable of performing work; but it performs work only while it is falling to the earth; and it becomes incapable of performing work when it has reached its lowest level on the earth's surface. So the waters of a lake elevated above the sea level are capable of doing work during their descent to this level. But the work is done neither in the lake nor in the sea, but only in the river down whose bed the water falls from the one to the other.

There are other modes of reaching a level than these, and work is done in them all. Thus the attraction of the moon heaps up certain portions of the ocean waters, and the tidal flow comes *from the effort of* this heaped-up water to regain its level. In like manner *the heat of the* tropic sun, by expanding the waters of the *equatorial oceans, lifts them* above the level of the condensed polar waters. *The effort to regain this* level produces vigorous ocean currents, of which *the Gulf Stream* is a well-known example. Again, *the heat of the sun similarly dis*turbs the level of *the air*; or it would be better *here* to replace the word "level" by "equilibrium," which is a word of more general application. The equilibrium of temperature in the air is disturbed by the solar heat. The atmosphere becomes more rare at one locality than another, and air flows from the dense to the rare region to restore the equilibrium of density. This is the origin of most, and perhaps primarily of all winds.

For the displays of energy here adverted to we are indebted to the action of the sun and the moon. Equilibrium in these particulars, already exists upon the earth's surface; but it is constantly disturbed by the influence of these distant spheres, and in the effort to regain it vigorous work-yielding forces are set free. The solar heat has done more than this; it has produced permanent disturbances of the equilibrium of force. Our coal beds are, in this sense, stores of force, which is capable of being set free under proper conditions. We might speak of the storage of heat in coal, as the storage of electricity is spoken of

PHOTO-MICROGRAPHY.

By DR. CARL SEILER.

All workers in microscopy, doubtless, appreciate the necessity of correctly recording, not only in writing, but also by means of pictures or drawings, many of the appearances seen in the field of the microscope. We can do this by drawing an outline of the objects observed, by the aid of the *camera lucida*; but not only does this require some expertise, but also a considerable amount of time, and even then the resulting picture will not be a correct representation of the field of the microscope, because it will always be tinged more or less by the imagination of the draughtsman, and will be more or less diagrammatical in consequence.

With photography, on the other hand, an exact reproduction of the image thrown upon the screen can be obtained, and in much less time than it takes to make even a moderately simple drawing with the *camera lucida*. It is the object of this chapter to give an idea of the means employed to obtain a photographic picture of a microscope object—means which are in the hands of every microscopist, and which do not require a great outlay of money.

A room with a southern exposure, which can be darkened; a mirror, movable in all directions, outside of the window; an achromatic combination of lenses of from eight to ten inches focal length; a microscope which can be tilted as to be horizontal, and a stand to hold the screen and sensitive plate, are all the apparatus absolutely necessary besides the chemicals used in ordinary photography.

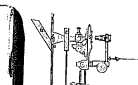


FIG. 1.

These different pieces are disposed of as follows (FIG. 1): The mirror (*a*), which should be eight or ten inches long by about four inches wide, is attached to a board which fits into an opening in the dark shutter of the southern window, and is to be moved by rods from the inside. Instead of this mirror, or in conjunction with it, a heliostat is of great advantage to throw the light of the sun constantly in one direction, for, if once adjusted, it need not be disturbed, and thus a great deal of time is saved. Until recently such an instrument was too costly for the use of students, but of late Mr. Kuebel, of Washington, D. C., has put a heliostat in the market which works very satisfactorily and which is sufficiently low in price to be within the reach of many who desire to work in photo-micrography. The heart in the shutter has in its centre a circular opening containing an combination of a one-fourth portrait photographic lens, horizontal position, so that the axis of the tube is in a line with the axis of the achromatic combination, and about half an inch from the back combination of the tube-stage condenser (*c*). The eye piece is then removed from the microscope, and the tube lined with black velvet, to prevent internal reflection, as far as possible, and the whole apparatus is covered with dark cloth, to prevent stray rays of light entering the darkened room.

This done, the sun's rays are reflected from the mirror outside the window, through the achromatic combination, which acts as a concentrator and throws a powerful light through the condenser, through the object on the stage (*b*), and thus a brightly illuminated image is formed by the objective (*o*) on the screen, which, later, when the negative is to be taken, is replaced by the sensitive plate.

This image, when thus formed, must be focused with the greatest care and accuracy, in order to obtain a sharp negative; and as the screen must be at some distance from the microscope in order to obtain the necessary magnification of the object, it is necessary to have some contrivance for turning the fine adjustment at a distance. For this purpose it will be found that a small pulley, placed alongside of the microscope, having an endless band running over it and the milled head of the fine adjustment, answers the purpose very well, when the axis of the pulley is connected by means of a universal joint to a fishing-rod, which by its sections can be made longer or shorter, thus bringing its end close to the screen.

The tube of the microscope, even when all internal reflection has been obliterated, still remains a drawback, inasmuch as it reduces the size of the image, or rather the disk of light, the more, the longer it is. There are, however, some stands made in which the tube can be entirely removed, such as the old Ross stand, and they are therefore very desirable for photo-micrographic purposes.

Any good objective of wide angular aperture and good definition can be employed for photography, provided monochromatic light is used in making the negative. When such is the case the visual and chemical foci fall in the same plane and a special correction of the objective for photography becomes unnecessary.

Such a light is obtained by passing the rays of the sun through a cell containing a strong solution of ammonio-sulphate of copper (*c*) before they enter the substage condenser. I have found some difficulty in making the cell containing this solution, as the copper salt will dissolve almost any cement, and if exposed to the action of the air, very rapidly becomes decomposed, and the solution is thereby rendered useless for the purpose. I have used with satisfaction a cell made of a brass ring, lined on its inner side with lead or tin, having a thread cut on its outside, to which flanged rings are secured. Upon the edges of the inner ring a ring of rubber tubing is applied, and upon it a disk of plate-glass is laid, which is tightly pressed upon the rubber by the flanged ring. Thus a cell is obtained very similar to the round, flat spirit levels, and which will hold the ammonia sulphate of copper solution for months without change. In filling the cell care should be taken to leave room for a small air bubble, for if the cell is completely filled the heat of the sun's rays will expand the solution sufficiently to cause leakage.

This solution, besides giving monochromatic light, at the same time filters out almost all the heat rays from the light, so much so that an immersion lens may be used for any length of time without the drop of water evaporating.

At the present time, when dry plate photography has been developed to such an extent that it has superseded, in a great measure, the wet process, it has been thought that it would be the most simple, economical and satisfactory method in photo-micrography; but after repeated trials by myself, as well as many others working in the same direction, it has been found that it is not only more expensive, but also takes more time, in the long run. The reason of this is that it is impossible to judge, with any degree of certainty, as to the actinic power of the light forming the image on the screen by merely looking at it, and that a trial plate only will give an idea of the length of exposure necessary for a given day, time of day

objective, and subject, to be photographed. It is true we can expose a dry plate for trial, but then we must develop it immediately, and the time of developing a dry plate is about three times that of developing a wet one, and a dry plate is also about three times as costly as a wet one. Therefore the old wet collodion process is the best.

The collodion to be used should be an old one, and contain some free iodine. I have found that a mixture of "Anthony's red labeled" and "Medalion, glace, half-tone" collodions—both commercial articles—one five or six months old, gives very satisfactory results. The nitrate bath should contain forty grains of crystals of silver to the ounce of water, and should be slightly acidulated with nitric acid. The developer should be a weak one: twelve to fifteen grains of the double salt ammonio-sulphate of iron to the ounce of water, containing a few drops of a solution of gelatin and acetic acid as a restrainer.

After the negative has been fixed in the usual way, with hyposulphite of soda or cyanide of potassium, it is almost always necessary to intensify it, which is easily done by flowing the plate while wet with a watery solution of iodine until the film becomes white; then it is to be washed under the tap and flowed with a solution of sulphide of ammonium, which imparts to the negative a dark brown color, and thus strengthens its printing quality.

The object to be photographed should be as thin as possible, because the lens will depict only one plane of it, and is should present as much contrast and differentiation of its elements as possible; this is especially the case in animal tissues, and when high powers are used, the focus should be taken with the greatest care *for one particular point to be brought out*; a general focus not particularly sharp in any one point, will not give a satisfactory negative.

The screen upon which the image is formed should be of plate glass, having an extremely fine ground surface on one side—the side next to the object. Such a surface can easily be prepared by flowing the glass plate with a good negative varnish, and when this is set but not yet dry, lightly breathing on it, when an extremely fine and even frosting of the surface will show itself, sufficient to arrest and reflect the rays of light forming the image.

In photo-micrography, as well as in ordinary microscopy, proper illumination of the objects is of the greatest importance, and frequently a poor objective will show a better definition in the hands of a skilled manipulator than the best objective can when the light is not properly managed. In this one point lies the difficulty of photo-micrography, and it is the stumbling block over which so many fall who undertake to photograph microscopic objects.

As a general rule the best light is obtained when the back lens of the sub-stage condenser is about half an inch beyond the burning focus of the large condenser in the shutter, that is about eight and a half inches from this condenser, and when the light is *absolutely central*. But this distance cannot be strictly adhered to, inasmuch as different objectives require different illumination. In practice, I find that in order to obtain the proper distance of the condenser for a particular objective, it is best to put a blood-slide, upon which the corpuscles are in one layer only, on the stage, and project the image on the screen, moving the condenser backward and forward until, when sharply focused, no concentric rings are seen in the disks. The object to be photographed can then be substituted for the blood-slide, and the light will be found to be all that is desired. (*Compendium of Microscopical Technology.*)

PROFESSOR HELMHOLTZ will issue a collection of his scattered scientific memoirs in the autumn.

PLANTÉ AND FAURE BATTERIES.

THE annexed illustrations of the secondary batteries, which are exciting so much interest at the present time will, with the accompanying description, enable the readers to understand their construction. At the recent soirée given by the Council and academical staff of King's College, several forms of electric lighting apparatus were used; but that which attracted most attention was a battery of forty-four accumulators of Planté's design, working twenty-four Swan's lamps. The cells were charged in Paris by a Gramme machine, and were arranged in a series of four in cabinet boxes, the sets being coupled up in series. The current supplied by this arrangement, shown by a galvanometer in the circuit while the lamps were alight, was about twenty-three webers, and was perfectly steady. The Faure battery yielding an almost equal current during the whole time, until the charge became exhausted, when it broke down suddenly, without any noticeable warning. Mr. Spottiswoode also uses the Faure battery to work Swan

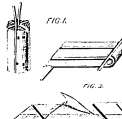

FIG. 1.

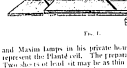

FIG. 2.

and Maxim lamps in his private house. Figs. 1 and 2 represent the Planté cell. The preparation is as follows: Two sheets of lead of any be as thin as six at least will be used for one on the cells, separated by two strips of india-rubber, the whole being held up as shown in Fig. 1. The lead being first carefully cleaned, the cylinder now in position is half filled with a solution of one part of sulphuric acid and sixteen parts of water. An electric current is then made to pass through the cell; oxygen is then made to pass through the cell; oxygen is given off, and produces a thick cushion of peroxide of lead on one sheet; hydrogen is given off at the other sheet. If the current with which the cell has been charged be cut off, and the two sheets are connected, a current is produced, owing to the presence of the oxygen and hydrogen in separate contact with the surfaces of the sheets are charged, the cell being covered with a cushion of peroxide of lead; the other with lead reduced to a spongy mass. The cell is then complete, and in a state of electrical accumulation. This was Planté's first secondary battery. Subsequently he used the plan of separating the two sheets of lead by causing the cell taking the form of Fig. 2. He has found that it was necessary to have a small piece between the sheets to provide for the escape of the gases which were produced at the end of the charge; subsequently indiarubber beads were employed in preference to canvas. M. Planté also tried carbonate of lead, minium, &c., but without improving upon the results already obtained. The

with its 80,000 volts, and supply it by secondary 200-volt
dynamos or 100-volt dynamos, through proper distributing
wires, to the houses and factories and shops where it is to
be used for electric lighting, and sewing machines, and
lathes, and lifts, or whatever other mechanism wants
living power. Now the thing is to be done much more
economically, I hope, and certainly with much greater
simplicity and regularity, by keeping a Faure battery of
50,000 cells always being charged direct from the electric
main, and applying a methodical system of removing sets
of 50, and plugging on the town-supply circuits, while
other sets of 50 are being regularly introduced into the
great battery that is being charged, so as to keep its num-
ber always within 50 of the proper number, which would
be about 40,000 if the potential at the emitting end of the
main is 80,000 volts.

ON THE ARRESTATION OF INFUSORIAL LIFE.*

By Prof. Tyndall.

Three years ago I brought with me to the Alps a
number of flasks charged with animal and vegetable in-
fusions. The flasks had been boiled from three to five
minutes in London, and hermetically sealed during ebul-
lition. Two years ago I had sent to me to Switzerland a
[illegible] of similar flasks containing other infusions. On
[illegible]ore this year 120 of these flasks lay upon the
[illegible]ber little library. Though eminently putre-
[illegible]imal and vegetable juices had remained as
[illegible]ear as when they were prepared in London.
[illegible]part taking up one of the flasks containing an
[illegible]fect or removed infantile organisms it
[illegible]ed with organisms. He would find it more
[illegible]ded throughout, with massive flocculi moving
[illegible]he liquid. Exposure of the flask for a minute
[illegible]tercurrin water would cause both turbidity and
[illegible]ulation; and render the infusion as clear as
[illegible] distilled water. The turbidity and flocculi
are simply due to the coagulation of the liquid to a jelly.
This fact is some guarantee for the strength of the in-
fusions. I took advantage of the clear weather this year
to investigate the action of solar light on the development
of life in these infusions, being prompted thereto by the
interesting observations brought before the Royal Society
by Dr. Downs and Mr. Blunt, in 1877. The sealed ends
of the flasks being broken off, they were infected in port
by the water of an adjacent brook, and in part by an in-
fusion well charged with organisms. Hung up in rows
upon a board, half the flasks of each row were securely
shaded from the sun, the other half being exposed to the
light. In some cases, moreover, flasks were placed in a
darkened room within the house, while their companions
were exposed in the sunshine outside. The clear result
of these experiments, of which a considerable number
were made, is that by some constituent or constuents of
the solar radiation an influence is exercised inimical to
the development of the lowest infusoria. Twenty-four
hours usually sufficed to cause the shaded flasks to pass
from clearness to turbidity, while three this time left the
exposed ones without sensible damage to their transpar-
ency. This result is not due to mere differences of tem-
perature between the infusions. On many occasions the
temperature of the exposed flasks was far more favorable
to the development of life than that of the shaded ones.
The energy which in the cases here referred to prevented
putrefaction was energy in the radiant form. In no case
have I found the flasks sterilized by insolation, for on re-
moving the exposed ones from the open air to a warm
kitchen they infallibly changed from clearness to turbidity.
Four and twenty hours were in most cases sufficient to pro-
duce this change. Life is, therefore, prevented from devel-
oping itself in the infusions as long as they are exposed to
the solar light, and the paralysis thus produced endures
them to pass through the night time without alteration.
If it is, however, a suspension, not a destruction, of the
germinal power, for, as before stated, when placed in a
warm room life was invariably developed. Had I had
the requisite materials I should like to have determined
by means of colored media, or otherwise, the particular
constituents of the solar radiation which are concerned
in this result. The rays, moreover, which thus interfere
with life must be absorbed by the liquid or by its germinal
matter. It would therefore be interesting to ascertain
whether, after transmission through a layer of any in-
fusion, the radiation still possessed the power of arresting
the development of life in the same infusion. It would
also be interesting to examine how far insolation may be
employed in the preservation of meat from putrefaction.
I would not be understood to say that it is impossible to
sterilize an infusion by insolation, but merely to indicate
that I have thus far noticed no case of the kind.

PLANTÉ'S RHEOSTATIC MACHINE.*

Translated from the French by the Marchioness Clara Lanza.

Ruhmkorff's electric induction machine has proved in the most satisfactory manner that by the intermediary of inductive action, we can transform voltaic electricity into electricity of high tension. M. Bichat has likewise shown that by the same means, currents of high tension can be changed to currents of quantity, analogous to voltaic currents. M. Planté, with his secondary pile, has rendered this demonstration still more emphatic, and as his experiments demanded a greater tension than he was able to produce with his batteries, he undertook the manufacture of an apparatus by which he could obtain very notable discharges of static electricity, capable of forming at will, long thread-like sparks, or short, thick ones. In this way he was induced to make the battery of which we are about to speak, and which he calls the *rheostatic machine*.

Although this apparatus (fig. 1) was presented to the Academy of Sciences and exhibited to most of the physicians who witnessed M. Planté's fine experiments, it is as yet, but little known. Why this should be the case we are at a loss to understand, for it is one of the most perfect machines that can be employed in experiments of static electricity. Had the apparatus borne a foreign name, we are confident it would have attracted considerable attention long ago. It is much to be regretted that we are so constituted in France, that whatever is invented by an unknown man, a *savant* who does not rejoice in an established position or who is not a member of some scientific coterie originating from a celebrated school, is looked upon entirely as a matter of subordinate interest. "It is only an amateur's work," we hear on all sides for awhile and then the subject is dropped forever. In England it is quite different. Amateurs such as Grove, Gassiot, Warren, Delarue, Spottiswoode, Lords, Rees, Lindsay, Raleigh, Elphinstone and many others, find their efforts are appreciated as they deserve to be, and no one ever thinks of inquiring whether they are *savants* patented by the government or not.

M. Planté therefore, not being among the last-mentioned, was forced to meet with indifference which he forcibly overcame later by the fine work he performed with his accumulators. He was not so successful, unfortunately, with his rheostatic machine, and for this reason we shall dwell a little upon the important results it has afforded us.

M. Planté's machine consists of a series of condensers with mica plates, parallel one with the other and capable of being charged and discharged in a manner similar to the secondary batteries without any other alimentary electric source than these latter.

The various pieces composing the apparatus must be

* *La Lumière Électrique*, August 6th, 1881.

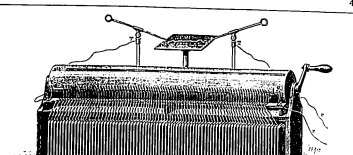

Fig. 1.

taken apart with great care. The commutator is formed of a long cylinder made of hard rubber. It is furnished with longitudinal metallic bands destined to connect the surface condensers, and crossed by pieces of copper wire bent at the ends, the object of the latter being to unite the condensers of tension. To this end, metallic wires, fashioned like springs, rest upon the cylinder and are associated with the two armatures of each condenser by very fine copper wires covered with gutta-percha. They are attached to an ebonite plaque on each side of the cylinder, and the latter can be made to rotate rapidly and continuously by means of a set of wheels. The final springs are separated considerably from those preceding them, in order to prevent the electric sparks from dis-

Fig. 2.

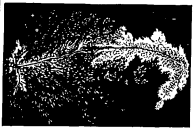

Fig. 3.

charging between the tension poles of the rheostatic machine and those of the secondary battery.

The mica plates in the condensers are 0m 18 in length and 0m 14 in breadth. The armatures are made of tinfoil. The edges of the condensers are rendered adherent by frames or simple ebonite plaques. These give them more rigidity and cause them more readily to maintain a vertical position, one beside the other, without coming in contact.

When the cylinder is so turned that the longitudinal metallic bands come in juxtaposition with the springs, the armatures in an even range with all the condensers unite on one side, while those in an uneven range are joined on the other, forming a single condenser of large surface. The armatures discharge by causing the right hand boundaries, which can be easily distinguished in the figure, to communicate with the poles of the battery.

When, on the contrary, the cylinder is so turned that its transversal pins are presented to the springs, all the charged condensers are connected in a series or in tension. The armature of the farthest condenser on the left, communicates with the last spring on the other side of the cylinder and ends at branch T of the excitant. The armature of the final condenser on the right communicates with the spring next to the last, and this spring unites with the last metallic pin traversing the cylinder. The last spring placed in the opposite side of the cylinder communicates with the other branch T of

the excitant. While the condensers are thus connected, the pole, or battery, which charges the apparatus, is entirely beyond the circuit.

M. Planté has constructed rheostatic machines of different sizes. The one here represented is supplied with eighty condensers. The commutative cylinder is 1m one meter long and 0m.15 in diameter.

When this cylinder is put in motion and the machine connected with the battery of four secondary couples, we perceive, as the charge begins to act upon the commutator, long lines of sparks at those points where the metallic contact is effected. It becomes a tube of sparkling light and the effect is equally apparent when the discharge in tension occurs. At the same time we obtain a long spark at the excitant T T.

THE STORAGE OF ELECTRICITY.*

BY SIR WILLIAM THOMSON.

The first and most obvious use of Faure's accumulator was stated by the author to be the production of electric energy at the most convenient time, and to keep it in store until it could be most conveniently used; but its largest use in electric lighting would be to allow steam or other motive power and the dynamo to work economically all day, or throughout the twenty-four hours when the communications were such as to render that economical, and then storing up the energy so that it might be available when the light was required. There was also a very valuable use of the accumulator in its application as an adjunct to the dynamo, in order to fulfill the first condition of giving greater regularity to the light-giving current and storing up an excess of surplus in such a manner that the stoppage of the engine would not stop the light, but only reduce it slightly, and so also that there would always be a good residue of two or three hours' supply of full lighting power after the driving machine was stopped, or a supply of light for eight or ten hours for a diminished

* Abstract of paper read in Section A, British Association, Southport.

number of lamps. It was obvious that great economy and important practical results were to be obtained by the use of such a system, provided that the expense of the storing material and the magnitude and the lasting power of the apparatus that it involved were not prohibitory—were not such as run away with whatever gain there might be in the principle. The subject was altogether in its infancy, and we must wait a fuller information, both as to its practical and its economic sides. So far as estimating electrical quantities was concerned, we must hold our hands until, along with the incandescent lamps given us, there was a statement that they would continue in action, giving out so many candles' power approximately, when so many volts were applied to them, and during such and such a time.

THE DE MERITENS SECONDARY BATTERY.

A MONGST the interesting exhibits at Paris is a secondary battery, the invention of Gaston Planté, de Meritens, which, it is said, is superior to the Faure. In its first form it consists of a sheet of lead 7mm. (.275in. nearly) thick, folded and rolled on itself in such a way that the sheet at each end is constant, and a series of triangles are made. These triangles are entirely filled by sheets of lead 2mm. (.078in. nearly) thick, and placed in contact with each other and the bounding sides. The leaves of lead foil are soldered to the sides, the ends, and a bigger, left in front, a "pole," and the bottom are placed in an ebonite box, perforated and covered with glass by a space of 9 mm. (.354in.) at the Exhibition in a battery of 50 elements, each 0m. (2·95in.) high, and 0m. 25 (9·84in.) thick. The bath consists of dilute sulphuric acid, 1 part of acid to 9 of water, and requires no renewing for months of clock or fuel enveloped, while the peculiarity of the construction leaves the leaves by a current very little altered, and is, moreover, from the arrangement of the plates, very little liable to become disturbed. M. de Méritens has also observed that the folded plate is of very little use, and that it is found necessary to employ plates of lead 1mm. thick, the thin ones 2mm. thick, being nearly all burnt away. The density of the current will now be much 1·5cm. wide. Several thousands of the thin leaves 0·005in. thick) will be placed upon one another in such a way as to form a vertical parallelopiped, one of the wider faces of which will be covered with the solder, and the strips formed by the leaves will be connected to it. In this way the weight will be considerably reduced, and the efficient surface largely increased. When once properly formed the battery is said to have a very large storage capacity compared with its weight, and it must be acknowledged that it is the simplest form of secondary that has yet been devised.

THE ENGLISH MECHANIC
AND WORLD OF SCIENCE.

THE STORAGE AND TRANSMISSION OF POWER.

MURRIE is abundant evidence in the proceedings at the meeting of the British Association to show that we are on the eve of a great revolution in our methods of utilising the available sources of energy. Sir W. Thomson, in the Section of Physics, and Sir W. G. Armstrong, in the Section of Mechanics, both addressed themselves to an elucidation of questions which are just now attracting the attention of mechanical engineers and physicists; and the modern developments of electric science warrant the boss of confident anticipation in which the two presidents spoke of their respective sections. A few years ago it was pointed out by a distinguished savant that the economy of steam-power had made considerable progress in the preceding decade, and as the advance towards perfection was still proceeding, it was not impossible that in another ten years we might reach a limit beyond which it would be hopeless to expect much progress. Events have not altogether borne out that expectation, and it is now recognised that the advance has been smaller in the last than it was in the preceding decade. Engineers are not at the present day in a hurry to write the word "finality" on their designs, but they are compelled by experience the fact that they are rapidly approaching the limit beyond which they cannot hope to progress. Just as they approach that limit, however, a new field opens to view, and the possibilities of advance in other directions attract their attention. The results obtained with the modern forms of dynamo-machines, the capabilities of Faure's installation of the comparatively old form of Plantè's storage battery, and the suggestion of Dr. Siemens that it is possible to utilise the immense power such a waterfall as that at Niagara, have given rise to speculations which, in the immediate future, may play a very important part, and the recent exhibition in Paris will direct the attention of many minds to a subject of growing interest. Sir W. Thomson, in his address to Section A, reviewed the sources of energy which man can utilise, and dwelt with special emphasis on the value of wind and water-power in combination with the artificial production of electricity. Sir W. Armstrong, in his address to Section G, drew attention to the fact that we have nearly reached the limit of possible development of the steam-engine, for, as he pointed out, the advantage to be derived by increasing the range of temperature is seriously discounted by the enormous waste of heat in the escaping gases and by radiation, while introducing mechanical difficulties and dangers that it would be better to avoid if possible. Mere increase of pressure is not an altogether unalloyed gain, and even if we can improve the steam-engine to the utmost extent at present deemed possible, it would still be a wasteful though undoubtedly a valuable servant. The steam-engine, which is really a heat-engine, acts by expansion of volume—a principle which is known to be essentially wasteful, whereas electricity operates by, for want of more explicit terms, what we call attraction and repulsion, thus producing motion in a manner which is subject to no greater loss of effect than attends the motive action of gravity. If we could produce electricity with the same facility and economy as we can produce heat, the gain would be enormous, and the question then arises whether we cannot actuate dynamo-machines by natural forces, and save our coal for other purposes. As a secondary motor, the dynamo-machine has already been utilised in several ways, and if we can actuate it by some power which is at present allowed to run to waste, the gain will be just the value of the coal and the interest of the capital that would otherwise be expended in laying down motive-power engines. Of the available sources of energy, the other than fuel, we have wind-power, water-power, and tidal-power; but, so far as the latter is concerned, it is, as Sir W. Thomson has shown, somewhat comparatively insignificant. In wind-power and water-power we have agents which cost nothing, and though, so far as the latter is concerned, in this country we have little more than the power of running water, the former may possibly, with the aid of recent inventions, be turned to good account. Sir W. Armstrong, in his address, reviewing the known means of obtaining electricity, pointed out that, until we can make the combination of coal with oxygen directly available for the development of electric energy, there seems to be no probability of obtaining the current from chemical action at such a cost as would supplant heat as a motive agent. Coal, and the other hydrocarbons, are the only abundant and cheap bodies which have their chemical affinities unsatisfied, and are, therefore, capable of evolving energy when combining with oxygen; and, although a method of storage would enable us to use water and wind-power for the production of electric currents our dynamo-machines will probably, for some years to come, depend mainly on coal as their prime mover. It is not impossible that with some form of gas-battery we may be able to use coal directly in the production of the electric current, and it is probable that future developments of the thermo-electric pile may place us in a position to obtain sufficiency of current by a direct application of heat; but at present the former idea is only in the laboratory stage, and the thermopile is rather more wasteful than the steam-engine. As Sir W. Armstrong put it, however, the vice of the steam-engine lies in its inability to utilise heat of comparatively low grade, while it wastes an enormous quantity up the flue of the furnace. If we could utilise that waste and the energy of the engine itself by a supplemental machine acting on the principle of the thermo-electric battery, we should approach very near to the possible theoretical economy. By whatever means obtained, however, it is certain that electricity will play an important part in the world of mechanics as a motive power, though for some time it may be in a subordinate character, as a sort of handmaid to the steam-engine. Sir W. Armstrong has himself drawn down a small but very useful illustration of the manner in which electrical appliances, to transmit its energy to a considerable distance, and there are many places where natural forces are available for producing power to be transmitted to situations in which it can be conveniently utilised. We give elsewhere some notes by Sir W. Thomson on the possibility of distributing the gigantic power of the falls of Niagara, the scheme depending for its success mainly on the practical utility of Faure's accumulator; but the idea is one that in different shapes has occurred to many investigators and experimentalists. If we can store in an economical manner the current produced by our dynamo-machines, we see then and there ready to take a large step in advance, and even if the storage should prove to be a rather costly operation, there are still many instances in which it could be employed with advantage. Mr. Stone has tested Faure's accumulator in connection with an installation of his lamps, and has expressed the opinion that it is the very thing wanted to make electric lighting all that was needed, while, as our readers will remember, Mr. Rankin Kennedy has explained in our columns the method in which he utilises it for a similar purpose (pp. 284, 308, Vol. XXXIII.). By means of the accumulator, electric energy, generated by a

THE AMERICAN ENGINEER. 157

THE CAVETT & McKNIGHT SHEAR

A visit to the Siemens-Anderson Steel Works at Pittsburgh, would give the reader an opportunity of witnessing the operation of a gigantic shear, recently put there, and which has attracted considerable attention. It is said to be the largest shear in the United States and weighs some 70 tons. It is designed to cut steel blooms eight by eight inches, or plates 36 inches by 1 inches, but. It does the work with the greatest ease and alacrity, and has already cut blooms seven inches by eleven inches.

This beautiful piece of machinery is about sixteen feet in height, while the body of the shear is nine feet and a half wide. These figures give but a faint idea of the grand proportions of the machine. The roller table attached to it is 22 feet wide. The shear is driven by continuous gear, and the crank or punch is thrown off by an independent steam cylinder. The fact that the gear wheel by itself weighs exactly four tons, gives one some conception of the immense power of the machine and how it accomplishes the feat of cutting blooms of the proportions mentioned above. The top shaft is 12 inches in diameter, of steel, with a wrought-iron eccentric of a weight of 1,500 pounds. The whole is driven by an 8x by 16 vertical engine. It is considered one of the great curiosities in the line of steel mill machinery to be seen in Pittsburgh at the present day.

Messrs. Cavett, McKnight & Co. manufacture this and a great piece of machinery, whose works are at 32 to 40 Penn avenue, Pittsburgh, are pushing an enviable reputation for large work, and we are pleased to be able to present an illustration of this, their latest addition to the examples of the progress in mechanics of the United States.

The machine was designed by Mr. David Shaw, of the Siemens-Anderson Steel Works. See illustration, page 156.

THE STORAGE OF ELECTRICAL ENERGY.

As the question of the storage of electrical energy is receiving so much attention in the discussion of the features of the Faure secondary battery, we venture to reprint extracts from the two leading engineering papers of London, on this subject. We begin with the following from the *Engineer;*

"A great deal has been written and said on the subject of the storage of electricity by means of Faure's secondary battery. That M. Faure has succeeded in improving upon the Plantè pile has been known for some time to scientific circles, but no undue importance was attached to the fact. Of late, however, most extraordinary stories have been set on foot; and the columns of the daily press have announced that storage is a fait accompli, and that before the close of gas-lighting is all but over, and that the ship of the immediate future will be propelled by electricity. We have contented ourselves up to this moment with an announcement of the nature of M. Faure's invention, and we have refrained from doing more lest we should inadvertently lend the invention a notoriety it does not deserve. M. Faure has been known for years in France, and there is good reason to believe that a company to work patents has already been formed in Paris, and that an attempt to form a similar company in this country will soon be made. The most exaggerated claims have been put forward for the invention—claims so exaggerated that there was reason to think that no one could be fools enough to believe them. Unfortunately, however, Sir William Thomson unwittingly wrote a letter to the *Times*, which appeared on the 26th inst., and which might easily be used with great effect by the promoters of a company. Sir William Thomson told the world that he had carried a million foot-pounds with him stored in a space of one cubic foot. This sounds very large, and the daily press in certain cases became more enthusiastic than ever. But large as "a million foot pounds" sounds, it is really very little, and Sir W. Thomson has, we feel certain, been misunderstood, and his incautious words have been made to imply what he never meant them to convey. Before going further we may explain that the force stored up in Sir W. Thomson's "unit of electricity" would not drive a 1-horse power dynamo-machine for more than half an hour, even if all the energy it represented could be made available by employing mechanical work. The latter expedient is not as a matter of fact there is no electricity available, over stored up in the form of mechanical energy, for the purpose of actual galvanic battery, the duration of release action is but short.

As the colons of the Faure battery to notice as a money-making invention we are bound to say we presume to explain what it is a property of, and in language—language which will not, perhaps, please the electrician, but will, nevertheless, convey to the reader who knows nothing of electricity a very good idea of the action of this wonderful box, about which so much is being said. Imagine a box of any convenient size, and which we much be better pleased in a weak acid solution, and kept from touching each other by means of cotton or cotton wool, or some such substance. If, however, a wire be used to connect the two plates, what is called galvanic action takes place. A current of electricity passes through the wire, and the zinc becomes rapidly oxidized. After a time the zinc will all be oxidized, save a small portion behind, which is protected by the oxide from contact with the acid. When this happens, the action of the battery ceases. Now let us suppose that a powerful current of electricity from another battery is driven in an opposite direction through the first-mentioned battery; the effect would be to undo what had been done, the zinc would be deoxidized and ready for work again, and if metallic contact were prevented, the battery might be kept ready for use for a considerable period. In practice the result we have indicated cannot be secured with zinc and copper, for reasons which we need not stop to explain. We have stated that it would, because the statement conveys a clear idea of what takes place in the Faure battery; for although deoxidation of zinc cannot be effected practically in the way indicated, it is possible so to act on an oxide of lead as to produce an analogous effect. The Faure battery consists of a strip of lead covered with red lead Pb_3O_4, the red lead, which is an oxide or rust of the metal, being kept in place by a sheet of felt. Two such lead plates having been prepared, they are rolled up together like the spring of a watch. This couple is then immersed in an acid bath and a current of electricity from a dynamo machine is driven through it. After two or three repetitions of the process, it is found that the red lead coatings on the two plates have undergone chemical change, one plate having been converted into peroxide of lead PbO_2, while the other is converted into metallic lead. By establishing conditions under which the peroxide loses some of its oxygen and the metallic lead gains some, a current of electricity can be obtained at once. Such, in few words, is the principle of the Faure secondary battery. It contains no electricity, but its parts are in a condition to produce a certain quantity of electricity at will, just like any other battery. The peculiarity of the Faure battery, it is said, that the current produced is powerful, very large in quantity, and high in potential. But this may be said of many other batteries.

"As to the value of such a battery as a mechanical agent, we have to bear in mind first that it creates nothing. It can only give back a portion of the energy expended in producing the chemical change in the red lead, and there is every reason to believe that if employed to turn the best dynamo-electric motor to be had, and more than 50 per cent. of the original energy would be given back. Thus, instead of 1,000,000 foot pounds in a box of one cubic foot capacity, we should have but 500,000 foot-pounds effective. But the great drain persistently urged for this Faure battery is levied in the idea that it represents vast concentrated energy—that nothing in parallel in this respect is to be found in the whole world. Thanks are due to Professor Ayrton, Professor Perry, of Dawn's College, who lead no time in replying to Sir W. Thomson's statements. The means of storing and re-storing mechanical energy," writes Professor Reynolds, "form the equivalent not only of Sir William, but of every educated mechanic. It is, however, a question of degree—of the amount of energy stored in a certain weight of the energy-storing device. The lowest possible efficiency in electricity is 50 per cent., and the highest is probably 90 per cent. Looked at in this way, one cannot but ask whether, if this form of storage is to be the realization of our aspirations, it is not enough to multiply by two pounds of energy, to supply a young impression until we inquire what is a unit. Eleven million foot-pounds of energy is what is stored in one pound of ordinary coal. A unit of electricity, weighing 75 lbs., there was just as much energy as in 1¼ oz. of coal, which might have been brought from Paris or anywhere else in a waistcoat pocket, or, better still, in a cigar-case by letter.'

"Professor Reynolds here hits the precise point which required hitting. The Faure battery is not a form of energy, but a convenient form of storage up of energy, that its powers are really very insignificant as compared with other arrangements. For example, a cubic foot of water weighs 62½ lbs., and so is 12.5 lbs. heavier than the Faure battery which contains the equivalent of a million foot-pounds. To impart 1,000,000 foot-pounds of energy to a cubic foot of water is only necessary to raise its temperature 20.7 degs. Fahr. Now, it is obvious we may say that the work cannot be rendered available for the production of useful effect, and he is in a sense quite right; but so far as the bare statement that the Faure battery contains a million foot-pounds of energy in a small space is concerned, the assertion that a cubic foot of water when heated 20.25 deg. hotter than it was before, contains 1,000,000 more foot-pounds of energy, is equally true. Again, a cubic foot of air at a pressure of 300 lbs. on the square inch, and atmospheres, contains very nearly 250,000 foot-pounds of energy, and this in a more available form than the energy stored up in a cubic foot of air in a finely-concentrated state into a liquid. The solution of gelatine, say be accomplished in many ways. The simplest would be the compression of air, but as much as the Faure battery. It is true that a vessel of four cubic feet capacity would be required to carry 1,000,000 foot-pounds in this way, but the engine and reservoir taken together need not be larger than the Faure battery and its containing vessel taken together. We might, were it necessary, easily extend this list, and show that the Faure battery has really no claim to be expanded in its present form as much more than an interesting scientific toy. Twenty feet of coal gas will produce an indicated horse power per hour in a small engine. There is no trouble whatever in compressing 20 cubic feet into a space of 1 cubic foot. If anyone will take the trouble to carry a cubic foot of gas thus compressed from Paris to Scotland, he will be in a position to boast that he has done just four times as much as Sir William Thomson. But 20 cubic feet of gas at 300 lbs. pressure will produce a horse power hour; but 20 cubic feet of gas condensed twenty times represents 2,000,000 foot-pounds. Let us now, however, compare Sir William Thomson and his with the Faure battery. We have no coal gas. We do not know what it costs to charge a Faure battery, but we know that coal gas can be had very much cheaper."

An article in *Engineering* gives us the following: "A few weeks since the scientific world in Paris was deeply interested by a paper read before the Société d'Encouragement by M. Camille Faure, who, following in the steps of M. Gaston Plantè, has succeeded—according to M. Reynier, upon a new form of battery formed and accordingly—according to M. Reynier—to develop a battery in which, Plantè pile, the result being that a may be stored up as could be done by the Plantè pile, the result being that a large amount of force easily stowed up in small and easily portable coils, for electric lighting, could be stored up in places, delivered from house to house, and could be transported from place to place, differing only from power supplied from the great problem of a domestic motive power.

This solved.

"M. Faure's secondary battery is an application of a new discovery to the

poured quickly at the neck, and the gates cut, so as to whirl the iron and keep all dirt in the centre of the ingot, which is then allowed to cool.

When the mould cools, the cast iron in the ingot-end until the neck is about to freeze up. When you see it put it in, then with a sledge-hammer, so as to cause a pressure on the contracting shell, which would be liable to crack. When feeling, break the real slowly. It is better to make the gates as hot as possible, by howling them in the sand, as the iron will be closer and make a sounder casting. Ingots of 2 tons and upwards are poured against a cold, dry casting, the mould being about level, the pressure will be equal all around. Wherever there is a check or crack, you may depend that it is caused by unequal pressure of the confined liquid metal against the contracting shell.

THE DE MERITENS SECONDARY BATTERY.

AMONGST the interesting exhibits at Paris is a secondary battery or accumulator, devised by M. A. de Meritens, which is said to be superior to the Faure. In its first form it consists of a sheet of lead 2mm. (·078in. nearly) thick, rolled and relabled on itself in such a way that the sheet is in the form of a cylinder with a number of perforations. Over this brought a number of thin sheets of lead 2mm. (·078in. nearly) thick, and placed in contact with each other and with the cylinder. The leaves of lead foil are soldered together on one side, and a tongue is left to form a "pole." Two sections are placed in an ebonite box, separated from each other by a space of 2 cm. (·787in.), and from the bottom by a space of 5 cm. (1·968in.). The space between the forming a battery at the Exhibition is very small indeed, being but 10mm. (·393in.) long, and 5cm. (1·968in.) high. The battery has both coasts of dilute sulphuric acid. The battery is entirely of lead, and therefore the protection in the form of cloth or felt envelopes, while the material formed between the leaves by the current, is very firmly adhered, and is, moreover, from the porosity of the lead, very light. The inventor, M. de Meritens, is a professor of medicine at the Brussels Veterinary School, and the fabled plate is of very little use in the battery, and is scarcely more than a dead weight, the thin leaves, 2mm. thick, doing nearly all the useful work. Four pole of aluminum will now be made simply of 8cm2 strips of lead 2mm. thick, and 5cm. (1·968in.) wide, soldered to a strip of lead (·393in. thick) and 5cm. (1·968in.) wide, which is then soldered to the aluminum pole. The battery is very light, and is said to be very powerful. It is not clear what is the exact capacity of the battery, but it is stated that it is simply proportional to the number of leaves of lead foil employed, and that the capacity is 1 ampère hour per kilogramme of lead. The internal resistance of the battery is very low, and it is said that it is retained by stops which prevent the lead foil from touching. The battery is said to be very durable, and to stand any rate of charge or discharge that may be desired, and to be very efficient, only more nearly than one half of the energy put in is realized.

Dried feces of gelatine, thus prepared, dissolve with great readiness in water. On the completion of the process the gelatine is to completely dehydrated that it will absorb from the air only 2 or 3 per cent. of moisture. The presence of water is a problem, as it will known, it always attended with changes, as it is the source of many undesirable chemical treatment, to avoid such consequences, whether it unit fortuitous or not is extremely fortunate in the value in the arts. Once the greatest difficulties in the way of the use of gelatine in photography have to do the fact that dissolved in water it undergoes the changes in the temperature and hygroscopic condition of the atmosphere, and chemico-physical conditions are rendered valuables by such sudden and unconstitutable changes. The process of dehydration is entirely independent of atmospheric conditions, and may be so nice that its moisture is not absorbed by the air. The process of dehydration has already been referred to. Of the material used it is only necessary to state that, as the process is very rapidly carried on, and as the solution is not exposed to such an extent as it is when the gelatine is prepared, the operations are employed, there is no opportunity for the most foreign substances to become intermixed with the gelatine present. While the process is very simple, the difficulty of treating all gelatine solution, from whatever source they may be derived, it is peculiarly fitted for the purpose, as it is free from the mineral jellies or hydrocarbons obtained from fish-skins, silted or fresh, and also from other fish tissues.

SCIENTIFIC NEWS.

NOTHER comet is announced, this time by Mr. Denning, who first saw it on October 4, at about 10h. 30m. sidereal time, in the constellation Leo and Coma Berenices. The following are approximate positions on October 4, 10h. 30m. A.S. 174m. 3s. Dec. 21. Daily motion, 1m. 30s. eastward. Bright central condensation. Dim. Eight degrees. The first orbit of the original telegram has been received from the Astronomer Royal; but it is not clear whether that was a repeat of Denning's, or whether the comet was also discovered at Greenwich.

Mr. Wesley, of 28, Essex-street, Strand, sends us Part I. and the Introduction of Hilaire's "Excessive Pictures of the Moon." Mr. Gravatt, R.E., has published six gelatine plates of the Moon at different phases, which are being reproduced by photo-engraving. The introduction, which we have not yet had time to study, describes the Moon fully, in clear, and descriptive given in the beginning understand that the other pictures will respectively illustrate the Moon's first quarter, Sunset at Copernicus, and "the Earth-like on the surface in shadow" of the Moon. The publication of these plates will doubtless meet with a favourable reception in the de-cavern.

The International Geological Congress meeting at Bologna, adopted on the 20th ult., a resolution in favour of combining the collection of a general geological map of the world to a scale of one millionth of seven sheets, and has appointed to be Germans, and the other five to be Italians, from England, France, Spain, Austria, and Russia severally. The scale of the map is to be 11,000,000, and the nations of the work to be performed in Berlin.

The Institution of Civil Engineers has issued a circular inviting communications on the following subjects:—1. The best method of furnishing the same amount of water as the Manchester Corporation supply. By simply turning off the handle of a committee, the circuit was closed for the screaming current. It is suggested that there should be a central generator of electricity for furnishing as current at any time in case of fire, as well as for lighting purposes; and facilities should be given to enable promptly the electrical machine with the conducting materials (2) will be noticed that the figures are rather unfamiliar, and it would be interesting to know how much the pump really did. (3.)

DRIED GELATINE FOAM.

A METHOD of preparing gelatine in the state of foam—a state in which it can be indefinitely preserved, or in which it can be readily dissolved in water, is described by Mr. R. Brooks, of Hockley, Essex.

The gelatine is first dissolved in water, but it is subjected to violent agitation, or to violent agitation, or to the action of air-currents under pressure, whereby air is mechanically held in the solution, and it becomes foamy; and, second, by evaporating the water from the solution, and the foam by subjecting it to the action of cold, dry air. The evaporation may be by the mere circulation of air in a finely-comminuted state into a liquid solution of gelatine, say be accomplished in many ways. The simplest would be the compression of air, and is as much as the Faure battery. It is true that a vessel of four cubic feet capacity would be required to carry 1,000,000 foot-pounds in this way, but the engine and reservoir taken together need not be larger than the Faure battery and its containing vessel taken together. We might, were it necessary, easily extend this list, and show that the Faure battery has really no claim to be expanded in its present form as much more than an interesting scientific toy. Twenty feet of coal gas will produce an indicated horse power per hour in a small engine. There is no trouble whatever in compressing 20 cubic feet into a space of 1 cubic foot. If anyone will take the trouble to carry a cubic foot of gas thus compressed from Paris to Scotland, he will be in a position to boast that he has done just four times as much as Sir William Thomson. But 20 cubic feet of gas at 300 lbs. pressure will produce a horse power hour; but 20 cubic feet of gas condensed twenty times represents 2,000,000 foot-pounds. Let us now, however, compare Sir William Thomson and his with the Faure battery. We have no coal gas. We do not know what it costs to charge a Faure battery, but we know that coal gas can be had very much cheaper."

An article in *Engineering* gives us the following: "A few weeks since the scientific world in Paris was deeply interested by a paper read before the Société d'Encouragement by M. Camille Faure, who, following in the steps of M. Gaston Plantè, has succeeded—according to M. Reynier, upon a new form of battery formed and accordingly—according to M. Reynier—to develop a battery in which, Plantè pile, the result being that a may be stored up as could be done by the Plantè pile, the result being that a large amount of force easily stowed up in small and easily portable coils, for electric lighting, could be stored up in places, delivered from house to house, and could be transported from place to place, differing only from power supplied from the great problem of a domestic motive power.

This solved.

"M. Faure's secondary battery is an application of a new discovery to the

like period preceding. At the twenty-two clearing-houses outside of New York, the exchanges were larger in June than ever before in any month, and in the last quarter, half-year, and year, were larger than in any previous corresponding period in the history of the country."

PROGRESS IN SCIENCE AND THE ARTS.

Shipment of Railroad Iron by the Mississippi River.—The shipment of 9000 tons of railroad iron from Wales to Des Moines, Iowa, by way of New Orleans and the Mississippi River to St. Louis, is a notable event, says the *Railway Age*, especially as it is future, as stated, that it is delivered at Des Moines at $6 a ton less than the rail would have been by way of New York and thence by rail. What the rate would have been any other way over the canal and lake route from New York is a question. As long as steamers carrying grain to Europe from the ports of New York can secure return cargoes of railroad iron, they can afford to make low rates; and the demand for railroad iron in such large quantities must be deemed upon permanently, and the question then will be whether New Orleans can hold out sufficient inducements as a place of import to make it profitable for the steamers.

Gold Mining in Australia.—The statistics furnished in the report of Mr. Hayter, Statist to the Government of Victoria, continues to exhibit a most remarkable decline. The quantity raised in all these colonies since deposits of that metal were first discovered in 1851 is estimated at 60,000,000 ounces, valued at $1,250,000,000. By far the largest proportion has come from Victoria, where the gold-fields in 1859 produced only 758,-342 ounces, which is less than half the average annual yield of the same colony during 1870–73.

This Little Earth.—A writer in *Belgravia* kindly furnishes us with a few hints—a sort of rude measuring-rod that may be of use when our sense of our planetary importance becomes oppressive. It is only, he says, when we regard our globe as a member of the planetary system, and that system in turn as a unit among systems, that we feel how infinitesimal are its conformand how relatively insignificant it is. We may, for practical purposes, treat the orbit of Neptune as the circumference of our planetary system, and state the diameter of it therefore as about 5,480,000,000 miles. But if we could suppose all this vast plane converted into a solid disk, instead of being, as now, for the most part empty space, and if it were then given, by some means or other, a slightly luminous surface, it would appear to an observer upon the very nearest fixed star no more pretentious than a new shilling glittering in the sunshine would appear to an observer at a distance somewhat over a hundred yards. In other words, it would want fairly [illegible] of all.—We may [illegible] sphere, [illegible] sun-[illegible] ircumference of [illegible] elimate of

ENGINEERING AND MINING JOURNAL.
[JULY 9, 1881.

The "Box of Electricity."—The following letter from Professor Tyndall appeared in the *London Times* of June 17th. The letter has a special interest, apart from the clear description of a "secondary battery," because it gives the honor of the discovery to its rightful owner, and removes the perplexity occasioned by the use of the term "storage of electricity" and "box of electricity."

"SIR: Would you permit me to say a word or two on a subject of great public interest and of considerable public perplexity—I refer to the so-called 'storage of electricity'? The usual condition for the production of a voltaic current is known to be the immersion of two different metals in a liquid called an electrolyte. When two pieces of metal thus immersed are connected with a galvanometer, the existence of a current is declared by the deflection of the needle of that instrument. Substituting for the two metals two clean plates of platinum and connecting them with the galvanometer, the needle remains unmoved. The platinum plates being homogeneous, there is no reason why the current should start from one of them through the liquid rather than from the other. If such currents started, they would be equal and opposite, and, would, therefore, neutralize each other. In other words, with the two homogeneous plates of platinum we have no current.

"But let the platinum plates, after immersion, be detached from the galvanometer and joined, even for a moment, to a voltaic battery, the current which would destroy the homogeneity of the plates, for example, by oxidizing the octahydrated water, that liquid will be decomposed, a film of hydrogen covering one plate of the platinum, and a film of oxygen covering the other. These two films play the part of two different metals in the ordinary voltaic battery; and if the plates of platinum should be connected with the galvanometer, the current produced will be strong enough to dash the needle violently aside.

"The experiment may be varied in fifty or five hundred ways, and when, instead of the films of gas, solid layers of depolarized electrolyte on one or the other of the homogeneous plates, the duration of the current is prolonged. Several cells thus rendered active, through the agency of an extraneous current, constitute what is known as a 'secondary battery.'

"The discoverer of this battery was a man who, without pecuniary reward, or even the hope of such reward, almost sacrificed his existence in the investigation which resulted in the discovery. The name of this man was Ritter, a native of the small German village of Lieguitz. He died in Munich, penniless, exhausted by restless labor, poverty, and disorderly living. A public subscription was started to save his name and services ought not to be ignored at the present time. Other men labored and we have entered into their labors. Employing homogeneous plates of lead and rendering them non-homogeneous—that is, converting them, in fact, virtually into different plates—by the action of a voltaic current, M. Planté greatly intensified the effects obtained by Ritter. Faure has followed and improved upon M. Planté. Converting the plates of lead with minium, with the aid of the currents now [illegible] battery of great power and of considerable promise from a practical point of view."

"But I think scientific men have a right to demur to the phraseology in which M. Faure's extension of the discovery of Ritter has been intro-

hardened, and the two cones ground well together. The small screw which is fitted into the stem to keep the pulley up to its bearing is better if it is tight enough in its place without going home to a shoulder, as it can be adjusted more easily.

To finish this tool the front part into which the drills are fitted is all that has to be done; this is also made from a piece of round steel, and should be made as short as possible, in order that as little vibration as possible may arise. When screwed and fitted to its place, the small stem should be held in a chuck made to the babr, the instrument put together and driven from the over-head motion to drill the hole in the front where the drills fit. This is an important matter, as it is most essential that it should be quite true. It will be seen that the front is thin hexagon where it goes against the face of the pulley; this is to facilitate the removing of it when necessary. The drills also should be turned in their pieces in the same way as ordinary ornamental drills.

I am quite convinced that this addition will be duly appreciated by those who try it. I have had the pleasure of making a great many, and they have always given satisfaction. A careful inspection of the original would help materially, and I shall be glad to show it, or lend it to anyone for that purpose. In conclusion, I hope that these details, though somewhat lengthened, may be of as much service as many others have, judging from the correspondence I have received relative to them.

HOW TO MAKE A 2IN. ASTRONOMICAL TELESCOPE.

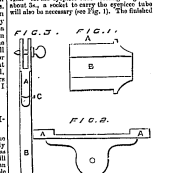
I WAS very glad to see the subject of the "effectiveness of a 2in. telescope" so ably dealt with by Mr. Dridle. There are doubtless many of your more fortunate readers who will smile at the fervour displayed over so small an aperture; but they should remember that as splendid work has been done with telescopes no larger than this; and also, that with a great many would-be students, the desire lies simply between the purchase of that size or none at all. The way in which I am acquainted with many of the new amateurs is considerably progress in practical astronomy, and who would certainly never have been tempted to provide themselves with telescopes had they not been able to gratify their tastes for star-gazing at a very reasonable rate, much lower in fact than the usual retail price of even such modest instruments. My object, in writing, therefore, is to describe how I, and others, who may be similarly situated, how they may very easily put together a thoroughly reliable 2in. achromatic telescope with two powers, brass tube, and which mounted on a tripod-stand, and still have some change out of a sovereign.

But, though I am desirous of showing how to the luxury of an astronomical telescope may be indulged in for so small a sum, I should be sorry to raise false hopes in the minds of those who by means have small be attempted. There must, for example, many of our readers to whom the highest prices for such a telescope would be just a mere trifle, but who would no less be keenly alive to the pleasure they would derive from the thought that it was to a successful issue of their own endeavors, rather than to the accidental possession of a long purse, that they were enabled to penetrate into the far depths of space. Nor is this all, for the experience gained in the manufacture will be of benefit, and cannot fail to be of value in the future selection and management of any other instrument they may hereafter possess.

As regards the choice of materials, I shall also like to say a few words. A great deal has been written about the necessary expense required by the use of "polished satisfactory and cheap" in both the microscope and telescope; but I may say I have yet to be convinced that either a tin tube or a roll of brown paper is at all suitable for the purpose. If a telescope is worth making at all, it is surely worth while to lay out an extra couple of shillings to give it a decent appearance, to say nothing of the superior solidity or of the convenience in getting a tube of just the right size, ready for immediate use at the nearest metal-merchant's.

The selection of the O. G. will first engage the attention of the operator. This should be of not less than 30 inches focus (solar), and should throw a clear-cut image of a pea or needle-frame without blur or haze at the edges. In testing the glass, the nearer the focus is to the object, the more the focus is to be less, the longer the focus will appear to be; some allowance should be made, therefore, for this peculiarity if the testing takes place, as it very likely will do, in the crowded interior of an optician's shop, and a still further allowance of about 3 inches must be made for the difference of focus between artificial and terrestrial objects; indeed, taking it altogether, an amateur would act on the safe side if, under the circumstances, he allowed a margin of 6 inches. The price of such an O. G. of Paris make, should not exceed 7s. or 8s.

The next step will be to procure a length (corresponding to the focus of the O. G.) of 2in. rolled tubing: 6 inches of 2in. and 12 inches of 1in.—for the eyepiece tube—cooling slipcaller sheet 5s., a socket to carry the eyepiece tube will also be necessary (see Fig. 1). The finished



socket, it must be remembered, should fit tightly into the 2-in. tube at A, and be just of sufficient size at B to allow the eye-tube to pass easily through. The pattern for this will have to be made by a turner, who must be warned to make the necessary allowance for the shrinking and swelling of the brass casting. The portion of the telescope is, perhaps, the most particular and difficult of the whole affair, so, to save trouble and expense to such as do not possess a lathe of their own, I shall be glad to forward a rough casting—chucked for the inner tube—on receipt of 1s. 6d. in stamps. The casting, as shown at A, Fig. 2, may be sunk into a piece of hard rubbing, and should fit sufficiently free to allow of an easy sliding motion. A safety pin and groove may be placed at C, if thought necessary.

The parts of the telescope are now ready for the lathe, and here I may say that the beginning may safely be left to the discretion of the amateur, or since it is, as regards its efficiency, quite a work of supererogation, he may if he much care enter with it altogether, or try its definition first and deal with it afterwards according to its merits.

Aldebaran.

(To be continued.)

THE TOMMASI SECONDARY BATTERY.

THE annexed illustrations show the construction of the Tommasi secondary batteries which have been patented by the Société Universelle d'Electricité Tommasi, of Paris. One of the modifications described is especially interesting, but the practical value of the invention obviously depends on its cost in actual working. It has been found by experience that

leather more than a year ago that firm, believing their workmen possessed a large amount of the inventive faculty which remained latent for want of sufficient encouragement to bring it out, offered small money rewards for improvements in any of the machines or processes carried on in their works and shops; and they instituted the awarding of these to a committee, who have recently formed their second annual list. Practically, this report is the first since the scheme has been in working order, and from it we feel that the committee have had under their consideration no fewer than thirty-four claims. The whole of these claims, we may take it, had some ground, though possibly in some cases those who made it, or had a slightly exaggerated idea of their importance. Nevertheless, they all represented some inventive work—whether successful or not was left to the committee to decide; and out of the thirty-four only eight have been rejected as unworthy of reward, while four remain for further consideration. We then find that during 1881, in one establishment, no fewer than twenty-two improvements have been made which are judged worthy of being rewarded by sums ranging from £2 to £5—sums which are practically acknowledged to be moderate as rewards. The committee, in fact, are now, we learn, empowered to grant sums of money exceeding £10, and also to give larger amounts than those which have been hitherto granted for improvements of the same degree of merit. Further, some of the improvements made are of so important a character, that provisions have been made for giving assistance in procuring patent rights; so that we may fairly say the scheme has been as successful as to have realised the anticipations of the firm. A large proportion of the improvements made by the workmen are in connection with the woodworking machines, some of which have been so modified that they now have a large variety of work, while others have been so contrived that they are used for many different kinds of work, besides the one for which they were designed. Other machines again, have been so improved that they do the same kind of work with greater safety, while sundry new processes and new methods have received awards from the committee. The results obtained in the short time reported on by the committee are highly encouraging, proving as they do in the most practical manner that there is a good deal of inventive tal-ent amongst our mechanics and artizans, and that if—as human in the majority of cases lessons there is no little encouragement for its exercise. We have always held that a Patent Law which encouraged inventors by putting protection within the reach of the poorest workman would lead to a great increase in the number of inventions brought to the Patent Office, and been to the United States, and the results of the experiment made by the Messrs. Denny are convincing proof that there are lots of inventive skill in the rank and file of workshops. Many of the improvements made by Messrs. Denny's workmen are in themselves of small importance, but still of importance in the workshop; it is clear, however, that the improvements which made machine capable of being manipulated by a boy of work on different patterns, but under circumstances would have not been patented and published for the benefit of other inventors.

NEW STORAGE BATTERIES.

THE UTILITY of the secondary battery or accumulator in any system of electric lighting appears to have been widely recognised, if we may judge from the number of inventions, patented and otherwise, which have come into existence within the past twelve months. Besides those already described and illustrated in our columns, there are at least three whose experimental trial is looked forward to with much interest, viz., those of Edison, Swan, and Brush—the latter, it is stated, being on quite a novel principle. Until a demand was created for these secondary batteries, no one thought of improving Plantè's simple device of two plates of sheet lead; but since the discovery of the value of red lead as a coating, which was made by M. Faure, many experiments have been at work, and these will probably shortly be as many different accumulators as there are inventors proper—that is, batteries in actual use, for the variation in Voltaic cell known and described are nearly numerous than is generally supposed. At a recent meeting of the Society of Telegraph Engineers and Electricians, Mr. Cromwell F. Varley, gave some curious instances of the manner in which inventions lie dormant or practically unutilised for want of a sphere of labour. It seems that as far back as 1861, in Patent No. 2555, he described forms of cells which have actually been re-patented three times—viz., by Sir C. Wheatstone, Mr. Smith and Mr. Varley. The battery first described in his specification is a modification of the Daniell; but Mr. Varley also inserted a description of the sulphate of mercury cell, in connection with the patent, chloride of lime as of insulation surfaces for storing up electricity. These latter devices were at the time well-known condensers composed of laminæ of tinfoil separated by sheets of some non-conducting substance, and connected at alternate ends to the pole of the battery. It is not unlikely that in the forgotten documents at the Patent Office there may be some other inventions which more nearly resemble the electrical accumulators we know of to-day; but it is obvious that the "earliest of the Patent will be the natural result, and the fittest will, no doubt, be that one which is cheapest. From this point of view it might be supposed that the secondary battery devised by M. J. Jacques, in which he employs a sheet of palladium as the negative element, would be of little practical utility; but with a sheet of lead as the positive pole, the battery is very powerful, even when of small dimensions, and notwithstanding the cost of the metal, it is not impossible that other circumstances may combine to render the use of palladium commercially possible. Three grains is said to absorb 900 times its volume of hydrogen; but as a sheet of this iron, with ammonium sulphate as the solution, absorbs still more, and as the cost of the latter may be found more advantageous. The positive plate of Mr. Rosser employs a cylinder of ferro-manganese for the positive, and steel iron as the negative element. Modifications of Plantè's secondary battery appear to have more attraction for inventors, probably because they are cheap and are cheaply constructed. On p. 613, Vol. XXXIII., we gave a description of one of these modifications, made by Mr. Dyer, who, working with M. Carpentier, has lately made further improvements. In one strip of lead, rolled into small tube by half a metre (say, 20in.) long, and of any suitable thickness—which probably means as thin as can be handled and worked—which he passes between the rollers of a corrugating machine, so arranged as to make the corrugations in an oblique direction. Each of these strips he folds in two, with a porous separator between, and scales the ends together. The corrugations are obviously to afford a passage for the escape of gases, and they are so arranged as regards the alternate position of positive and negative plates that they all point upwards. The soldered ends of the plates are at the top.

[From the "Journal of the Society of Arts."]

The Storage of Electricity.

By SYLVANUS P. THOMPSON, B.A., D.Sc., Professor of Experimental Physics in University College, Bristol.

[Continued from page 31.]

APPLICATION OF PLANTÈ'S ACCUMULATORS TO ELECTRIC LIGHTING BY INCANDESCENCE.

Faure's cells have already done good work in providing an efficient means of working incandescent lamps, such as those of Swan and Maxim, for domestic purposes. I have the pleasure of showing you to-night the result of passing through two chandeliers of Edison's little incandescent lamps the current generated by forty of Faure's accumulators. Here are also some of the incandescent lamps of Swan and of Maxim, lit up by the same means. I have to thank the representatives of the various companies for the courtesy that has put at my disposal these means of illustrating my discourse.

Careful and precise measurements have been made by Sir William Thomson and Mr. J. T. Bottomley, using from 29 to 30 Faure cells as a source of current to illuminate 24 of Swans lamps. These measurements have shown that the efficiency is very considerable, and that where from 35 to 50 such cells are available, the light produced by one lamp may range from 300 to 400 candles per horse power, the latter being measured as actually consumed in the lamp.

Carbon of lamp broke with small power, immediately after the measurement of the light was completed.

The foregoing statistics of one series of experiments are taken from the paper read by Sir William Thomson at the meeting of the British Association at York, September, 1881. From these experiments it appears that a high degree of economy in lighting by incandescent lamps is really attained. Should the accumulator be further improved, to reduce the percentage of waste between charging and discharging, accumulators will play a very important part in future installations, provided they can be constructed at a prime cost, lower than the present figures.

At the Paris Exhibition of Electricity, Faure's batteries have been doing excellent work. The following details of the separate installations will give an idea as to how many cells are required for a given number of Swan's lamps:

THEORETICAL APPLICATIONS OF ACCUMULATORS.

In an article on electrical storage, which appeared in *Nature* on June 2, 1881, I pointed out the usefulness of accumulators, in the following words:

"The uses for such secondary batteries may be of three kinds:—1. They may serve as portable supplies of electricity to be left and called for to exchange when *charged*. 2. They may serve to accumulate supplies of electricity from dynamo-electric machines, and store them until required for furnishing electric light or motive power on a small scale. 3. They may serve as equalizers of electric currents in a system in which the supply is liable to fluctuations. Suppose, for example, a dynamo-electric machine is employed to produce electric light. Any least thing which alters the speed of the machine, even for an instant, makes the light flicker and change in intensity; while the breakage of the engine-strap would at once cause total darkness. But if a secondary battery of suitable dimensions and power were inserted across the circuit between the dynamo machine and the lamp, the inequalities of the current would be greatly modified. When the light was not in use the battery would store up the current. If the engine failed the battery would at once put forth its power. It is probably in this direction that the secondary battery will find its unimportant field of useful-ness."

Of the first and second of these purposes you have an illustration to night. The modified Plantè cell and these Faure cells having been brought to this room charged, for the purpose of showing you their powers. The third possible use has been also emphasized by Sir William Thomson, who, at the Bath-usher meeting of the British Association, gave details of a science of automatic adjustments to make and break the circuit between the dynamo machine and the secondary battery, so as to guard the former from damage and the latter from waste.

As to portability, for such purposes as domestic lighting, the cost and risk of carting the heavy cells to and fro is probably prohibitory. For special purposes, such as those of gelenco-cautery already mentioned, the Plantè accumulator is certainly superior to the Faure, since it is lighter, and at the same time gives up its charge more rapidly, though in storage power for cells of equal bulk is less than that of the Faure.

MAXIMUM TEMPERATURE ATTAINABLE BY A CELL.

In connection with the subject of obtaining a high temperature by means of a cell, it may not be out of place to point out that the very high electromotive force of three accumulators (about 2·2 volts), exceeding that of my single cell of any other kind, carries with it the possibility of obtaining with such a cell a lower electromotive force. This discovery is due to Lovera, of Copenhagen, who, in a remarkable paper published (in "Wiedemann's Annalen") in August last, upon the relation between the conducting power of metals for heat and for electricity, has shown that the highest possible temperature to which a cell can raise any part of its circuit is proportional to its electromotive force. The highest point to which a Daniell's cell, however large, can raise a platinum wire according to Lovera is 3,237° above the zero of the Centigrade scale. The limited temperature for a Plantè or a Faure cell is 6,927°.

APPLICATION TO BLASTING AND TORPEDO FIRING.

The great calorific power of these accumulators, due as much to their small internal resistance as to their high electromotive force, is doubtless of great importance in the application to the firing of blasts and mines in great numbers. The old galvanic batteries now used might economically be replaced by one or two storage cells provided with a charging battery of half a dozen Daniell's cells, whose slight internal resistance would be thus accumulated.

APPLICATION TO PERFECTION OF THE TELEPHONE.

Another application of the secondary battery which has occurred to me, and which, on a small scale, I have tried with success, is in connection with telephonic transmitters. The problem is still room for improvement in the telephone; at the best, the speech it transmits is neither so loud, nor so distinct, nor so free from extraneous sounds, as might be desired. The fault lies almost wholly with the transmitters. They will not transmit loud sounds distinctly. The strength of the currents generated by the Bell telephone, used as a transmitter, is limited by conditions which are wholly inherent in it. Hence the possible strength of the currents transmitted from those which fall into the mouthpiece of a "microphone" or "carbon transmitter." My remarks must be understood as applying to the latter kind of instrument. If you put a very strong current on to a microphone, so as to make it, as you think, speak more loudly, the end is not attained. The points of contact are worn, there is a wildering and wheezing heard at the receiving end, and the speech degenerates into confusion. There is, then, a practical limit to which the strength of the current flowing through a microphonic current can be carried. Some of the transmitters in use employ three or four pairs of contacts, the current being carried through these either in series or in parallel. In the first of these two cases the resistance is only pushed beyond a certain limit, one only of the contacts usually does work by one stage. In the latter case, one only of the contacts is least. I the real work of transmitting—namely, that whose resistance is least. I propose to increase the power of a transmitter by employing a multiple microphone, so arranged that a fairly strong current shall pass through each point of contact, and that the current through each contact shall be independent of that through the rest. I therefore arrange all the individual microphones in parallel arc, in the line circuit, but provide each with its own battery. A hundred microphones thus united, and simultaneously acted upon by the voice, will each add its own quantum to the total effect in the circuit, and the result will be loud and distinct speech. But a hun-

Electricity as a Motive Power.

An interesting lecture has been given by Mr. W. Leahine, C.E., on the "Secondary Battery." Successful results, he promised, had been obtained in lighting a train experimentally with electricity on the Brighton line. Referring to the electric railway at Berlin, and the electric tram car in the Place de la Concorde, he stated that tram cars could be propelled by electricity in accumulators at one-third less cost per diem than horse power, irrespective of the capital sunk in the purchase of horses at £40 each. He had worked a sewing machine from an electric accumulator, and he saw no reason why trains should not be run by the same force on the Underground Railway without any locomotive whatever. Mr. Appleyard, fully indorsing the remarks of the lecturer, expressed his opinion that the forthcoming electric exhibition at the Crystal Palace will far excel that held in Paris. Thanks were given to the lecturer for his very able paper. In response he said that cells had already been prepared to prevent gyration in balloons.—*Times.*

The Storage of Electricity.

By Silvanus P. Thompson, B.A., D.Sc., Professor of Experimental Physics in University College, Bristol.

Introductory.

Science has of late made two advances, the ultimate importance of which it would be difficult to overestimate. Not many months before he was seized with the mortal illness which robbed us too soon of his rare and unique genius, Prof. Clerk Maxwell was asked by a distinguished living man of science what was the greatest scientific discovery of the last twenty-five years. His reply was: "That the Gramme machine is reversible." His far-reaching and philosophic mind had perceived that in this phenomenon, which to so many had seemed little more than a curious scientific experiment, lay the principle which, if rightly developed, would render possible the electric transmission of power, and, in the solution of this practical problem, bring about social and economic changes, the importance of which but few of us have even yet begun to realize.

If we could to-night summon up the noble spirit of the philosopher and ask him to tell us what recent scientific discovery came next in importance to this, I think we should receive the reply "that a voltaic battery is reversible." The reversibility in the action of the voltaic cell is the counterpart and complement of the reversibility of the Gramme machine; for while the one has solved for us the problem of *the electric transmission of power*, the other has solved for us the problem of the *electric storage of energy*.

The storage of electricity in such a form that it shall be available for producing electric currents, and for the electric transmission of power, is a fact of so great importance, both in science and in commerce, that no apology is needed for bringing the subject before the Society of Arts. *But the ogre is needed for bringing the subject before the Society of Arts. But the electric storage of energy, which is the end attained, must not be mistaken for the storage of that subtle agent, electricity itself.* A century ago it was thought that the Leyden jar provided a means of bottling up electricity itself. In one sense this may be true, though the fact remains that the more carefully we hunt for the charge of electricity condensed in the jar, the more difficult does it become to realize that there is anything there; and *it is doubly difficult to find, in the electric accumulator or storage cell, anything which can be called stored electricity.* In electric accumulators, such as those of Planté and Faure, electric currents are made to do a certain kind of work, which store of work can again yield us current of electricity. But, as a matter of fact, the particular kind of work done is, as we shall see, quite as much chemical as electrical. Just as in Sir William Armstrong's hydraulic accumulators, water forced into a vessel with a great pressure furnishes a means of storing mechanical power under such conditions that when we let it down it can do work for us, so in the electric accumulator, by which we want to store electric currents, we use a chemical storage, and the chemical work so stored can itself, as it runs down, set up electric currents in our wires, and do electrical work for us.

Before dealing with the various systems of electric storage that have been suggested, I purpose to lay down two important general principles. They are as follows:

Firstly, that no kind of storage of energy, mechanical or electrical, is possible, except by doing work in overcoming some force which itself opposes the process.

Secondly, that the action in which work is thus done must be one that is reversible; that is to say, to which there is an equal and opposite reaction.

ELECTRICAL ACTION AND REACTION.

"To every action there is an equal and contrary reaction." In these words Newton laid down the great fundamental principle of mechanical science. Its application is not limited to such mechanical reactions as the recoil of a gun, the return of a bent spring, or the mutual attractions of the planets, but reaches down into other departments of science. To Newton himself we owe the simple experiment in which he proved the extension of the principle to magnetic forces. He found the magnet to be drawn toward a piece of iron with a force precisely equal to that with which it drew the iron to itself. It was left to Newton's great contemporary, Robert Boyle, to demonstrate that the same law held good also for the force of electric attractions; an electrified body drawing a non-electrified one toward itself and being itself attracted with an equal and oppositely directed force.

But Newton himself showed that there existed another and deeper meaning to the law of action and reaction, when he laid down the famous comment* which, though forgotten until unearthed by Sir William Thomson, virtually anticipated the nineteenth century discovery of the conservation of energy. As understood in the light of modern dynamics, any "action"

* ("Postles on Nat. Phil.," Chap., II., Art. 20):—"Work done on any system of bodies has its equivalent in work done against friction, molecular forces, or gravity, if there be no acceleration; but if there be acceleration, part of the work is expended in overcoming the resistance to acceleration, and the kinetic energy developed is equivalent to the work so spent."

is which energy is spent and work done is found to have its corresponding "reaction" in the possibility of the energy thus stored being at some later time set free. That particular "action" of an agent to which Newton told us there was still an equal "reaction," when the action was measured by the product of its momentum into its velocity, was in fact nothing other than its *capacity for doing work*.

If you lift a pound of iron to a certain height against the pull of gravitation, the action implies the expenditure of a certain amount of energy, the equivalent of the work done. Precisely an equal amount of work (saving a trifling proportion converted into unuseful work of another kind—namely, heat) can the mass of iron do in falling back again; for by its fall it may do the work of raising another pound to the same height.

In the science of electricity and in magnetism the same fundamental principal holds good. Suppose, for example, energy to be spent in the following action: Let a heavy weight descend over a pulley, and in its descent cause the dino of a Holtz's electric machine to rotate; the work done in this case is electric work, the energy being expended not in moving matter against gravitation or any similar force, but in moving electricity against those electric forces which are continually urging it to run down to the dead level of equal and uniform potential. But our supply of electricity thus furnished can itself be made to do work, because it can thus run down and give out in another form the energy expended on it. Only let it be led by wires into the terminal poles of another Holtz machine, and it will drive it round, and by driving it round may be made to lift a weight. The reaction here is the converse of the action, and would be equal but for inevitable waste by friction and dissipation of the electric charges.

Another instance of electric action and reaction is afforded by the reversibility of dynamo-electric machines, such as that of Gramme, as mentioned at the outset. The Gramme machine can be used either as a generator or as a motor. If driven by the power of a steam engine or a gas engine, or by wind power or water power or hand power—in short, by any mechanical means whatever—it generates powerful currents of electricity, which may be used for producing electric lights, or any other kind of work that an electric current can do; the currents of electricity being due to the rapid movements of coils of wire fixed upon a rotating armature across a field of magnetic force, excited by the currents themselves in the same machine. If, on the other hand, currents furnished by any suitable source are led by wires into the coils of a Gramme machine, those currents will drive it round, and will expend their energy in producing mechanical rotation, causing the machine to be used as a motor.

Here I may remark, in passing, that the reversibility of the Gramme machine affords a means of electric, or rather of electro-mechanical storage. Suppose we want to store electric currents. Set them to drive a Gramme machine, and let the Gramme machine, by means of a pully, gradually wind up a very heavy weight. If, subsequently, we let the weight descend, it will drive the Gramme machine, and will generate currents as it runs down.

ACTION AND REACTION IN VOLTAIC CELLS.

We now pass to the more immediately important case of the reversibility of the voltaic cell, as of its chemical and electrical actions.

In the ordinary voltaic cells, currents of electricity are produced as the expense of a certain consumption of zinc and of acid. These materials may be regarded as the fuels of electric currents, just as coke and coal are the fuels of steam power. Like those fuels, they represent a store of energy. Everybody knows that when two bodies attract one another (as for instance the earth attracting a stone), and we do work in separating them, they possess the power of rushing together again, and of doing work; and, therefore the power of rushing together again, and of doing work; and, therefore, when so separated, may be said to represent a store of potential energy.

This is equally true in the case where we do work against the atomic attractions known as chemical affinity. Zinc has a certain chemical affinity for oxygen. To separate an atom of zinc from one of oxygen requires that we should do work, and then they have the chance of energy to be expended. When thus separated they have the chance of doing work in resulting, this work generally appearing in the form of heat. When a piece of coal is burned—that is to say, is permitted to unite chemically with oxygen—it *is* a store of energy *come down*, and manifests itself in the form of heat. A piece of coal represents a store of energy. So does a portion of food. A piece of zinc, for zinc can burn directly and bag of hydrogen gas; so does a piece of zinc, for zinc can burn directly and give out heat, or may burn indirectly by being dissolved in sulphuric acid, also giving out heat. A Daniell's battery represents a store of energy. A pinch of gunpowder also represents a store of energy. The amounts differ, it is true; and the rate at which some of these stores can be made available for use also differs widely in the different cases.

An ounce of coal represents an amount of energy which, if entirely expended in doing work, would raise 600,000 pounds one foot high against the force of gravity, or would do 600,000 foot-pounds of work. An ounce of gunpowder is stored about 10,000 foot-pounds of energy. An ounce of zinc represents a store of only 132,000 foot-pounds. An ounce of copper

ARTICLES.

THE TRANSMISSION OF POWER TO A DISTANCE.

ONE of the most valuable papers read at the recent meeting of the Institution of Mechanical Engineers, was that by M. Arthur Achard, of Geneva, on the various modes of transmitting power to a distance. The recent developments of dynamo-electric machines have, as will be remembered, drawn renewed attention to the subject, and the power wasted at such a place as Niagara Falls has been a favourite text for the lecturer. M. Achard has been studying the question for several years, and has now combined the results of his operations with an account of sundry practical experiments in a paper which, in the future, will be frequently referred to. The application of transmitting power have been the hydraulic, the compressed air, and the wire-rope, and each experience as has been gained in the former is not likely to recommend it to the attention of engineers. We do not, of course, refer to the use of a hydraulic power distributed over a factory or a railway goods yard, and for the use of a large waterfall as a source of power for the factories which may be established in its vicinity. M. Achard has already described (in a paper published in 1877) the application of hydraulic power to a number of factories at Schaffhausen, Fribourg, and Bellegarde. The water-power running to waste in Europe is sufficient to form a most feature looping for a little of it near his own factory, and as we have the photographs of the Mont Cenis tunnel turned all available falls to account when carrying out that gross and arduous undertaking. At Schaffhausen, however, where everything seemed favourable for permanently utilising and transmitting hydraulic power, the profits on the cutlay of capital has been very small indeed, in spite too, of suitable conditions, rapid extension of working, and careful management. At Fribourg and Bellegarde, where the conditions are not quite so suitable, the manufactories failed after a short and profitless existence, showing very clearly that cheap motive power is not in itself sufficient to create industries. Wire-ropes, for transmitting power to a distance, are simply a modification of the rope system, the only advance being the material of which the ropes are constructed. It is only on a par with the usual treatment of scientific subjects by French and foreign writers that the invention of wire-wire ropes for power transmission attributed to a resident of Ohio, although in reality no form or another, they were well known, but in this country and in America, practically before the alleged inventor had left school.

The principle on which this transmission of power is carried out are well known, being simply an extension of those on which ordinary hemp ropes are applied. The transmission of power by means of ropes requires that a shaft friction much greater than does transmission by toothed wheels; but ropes adapt themselves to conditions where gearing is out of the question, and by the use of large

pulleys, the friction is much reduced, the effect of the stiffness of the rope being also then comparatively insignificant. Where the distance is considerable, the transmission is divided into "relays" with a separate rope for each, and the relays are separated by "stations." Each station is provided with a horizontal shaft, and a double-grooved wheel, which is the driven pulley as regards the relay which terminates there, and the driving pulley as regards the succeeding relay. The power has to be distributed at intervals along the line, it is taken off at the stations, the rope there being adapted for the purpose. Sometimes a single rope is used, but where the power limit is placed at 500H., and the most length adopted in practice is about 4,921. The diameter of the pulleys generally employed ranges from 11, to 16ft., and with their shafts they weigh from 7½lb. to 11,233lb. in the case of single-grooved, and from 1,151lb. to 8,257lb. in the double-grooved pulleys. The slope of the grooves is a V rounded off at bottom and having a double-curve. The cases in which pieces of leather are secured to the grooves, which, in such a case, about three years, but wears out most rapidly on unsuitable pulleys which simply carry the rope and revolve at very rapid rates, the loss corresponding 4H. The speed of the ropes may, without inconvenience, be 1,000ft. per minute. At Schaffhausen, the ropes last on an average about a year, but it must be understood that the engineers do not wait for a rope to break before renewing it. Hence it is not unlikely that the life of a rope might be considerably greater, if, as soon as it commenced to fail, the work could be tolerated. Short life is a great fault in the transmitting power system by wire ropes, but they afford unquestionably a simple, and, for existing plant, often where other devices would be unsuitable or at a inexpensive. No little skill is needed to obtain the maximum amount of work and of durability, and though M. Achard gives formulæ, they require modification according to varying conditions which he specifies. When power has to be transmitted to the top of a very steep hill, instead of a relay station exactly at the top, it is better to have two intermediate pulleys, and to put the further away on the level. This at Bellegarde, where a height of 1126. has to be surmounted; this plan has been found best in transmitting the power of a couple of turbines. For the formulæ and details we must refer those interested to the paper itself, which will be published in the next issue of the Proceedings of the Institution of Mechanical Engineers.

Transmission of power by compressed air has, since the experiments made at the Alps during the long tunnels through the Alps became known, been a subject of discussion amongst engineers. Except for use in mines and for the purpose above mentioned it is not come into extensive use. Work of this kind, having been for inserting experiments, necessitates the use of air at high pressure, and hence results in much expansion; but the question of efficiency is for cases of the kind put in the background by the engineer, in consequence of the great advantages presented by the cheap power workings. It is, perhaps, not too much to say that the long tunnels through the Alps could not have been excavated at twice their cost, without the use of compressed air machines, which served a double purpose. As a means of transmitting power, however, the question of efficiency becomes of the first importance, and M. Achard says that the ultimate efficiency is the product of three partial efficiencies, (1) that of the air-compressing machine; (2) that of the pipes by which the air is conveyed, and (3) that of the machine which the air is to do the work. The essential condition required in an air-compressor is, that the temperature of the air during compression should be as far as possible constant; and, according to M. Achard, the most efficient method of accomplishing this is the one of the Col de Gothard machines was M. Colladon's suggestion, to inject a very fine spray of water into the pump-barrel, and thus bring it into intimate contact with the air to be acted. These machines, he says, had an efficiency of 78 to 82 per cent., but no subsequent tests appear to have been made. M. Achard has, however, made a number of facts bearing on the question, and his contribution will be read with attention. Just as water is used to cool the air during compression, so it is employed to heat it during expansion; and M. Achard describes Schaffhausen's compressed-air engines for tramways in the city of that name. The air-engine in this engine-tube on its way to the cylinder passes through a pipe double-grooves. This stove is heated by coke, and, after, at a small expenditure of fuel, is enabled to work expansively without serious loss from cooling. Referring to the transmission of power to a distance, M. Achard described the well-known Schmidt hydraulic engine, which resembles an oscillating steam-engine, and a turbine on Girard's system, in the setting of both these machines varies greatly with the surrounding conditions, and they scarcely afford a solution of the problem. Turning to the use of electricity as a motive power, M. Achard had little that was new to tell the Institution, and in the summary he stated that transmission of power by ropes furnishes the most economical result, and that where where wide distribution of the power is required, it is the only one to be preferred. As a kind of preface to a description of his system, M. Achard's Archimedean paper will be valuable; but at present there is no data, or at least not sufficient, to enable us to arrive at very definite conclusions. Electricians will naturally hail by electricity, and, so far as we can see, that promises to solve the problem in a very satisfactory manner; but the question belongs to the future, when competitive experiments may have elicited the attention of engineers on the lines which will lead to the greatest amount of success. Electricity has been applied to the transmission of power, and in a few cases has answered admirably; how far it can be economically employed in other cases there are no useful data available in forming the estimate. We know what has been done by Mr. W. Armstrong and by Dr. Siemens, and we look to a continuation in the unsettled country like the United States to supply us with useful information on the subject. In Switzerland water-power is extensively used, but, as we have already established, there is little likelihood that electricity will make experiments with dynamo-electric machines; hence it is only where waterfalls are available that the experiments we want are likely to be made, and only there when a demand for power is created. Manufacturers, as a rule, will not settle in districts where cheap power is the only attraction, and if the cheap power is only transmitted to their premises they will gladly do so. In the course of the discussion which followed the reading of the paper, Mr. Siemens was generally pledged, and some useful suggestions were made which mechanical engineers will keep in mind. Mr. Schönjander mentioned that his attention had been drawn to another means of transmitting power to a distance, by means of steam in properly perforated pipes—a method which is just now talked about in the United States, but which is scarcely within the compass of the question. What is wanted is a successful method of utilising waste power—that of waterfalls, of running rivers,

THE STORAGE OF ELECTRICITY.

At a recent meeting of the Newcastle-upon-Tyne Chemical Society, Mr. J. W. Swan read the following paper:—

"Before I commence," he said, "the term "voltaic accumulation" to him also. But more than this, we owe to Plante the rich results of a life devoted almost entirely to the subject of its connection with it the name by which he employs the phrase "voltaic accumulation" in a double sense—as meaning a thing stronger, and to signify cumulative effect. It is in this last sense that the term is generally used by M. Plante, and it is, or to which I shall confine myself. Now, M. Plante has chiefly directed his attention. One of his principal objects has been to construct a battery which should combine with high tension effects usually obtained from the fricational discharge of an insulating plate machine, the continuous and comparatively late electricity and of fricational electricity were so widely different. Voltaic electricity, he says, is essentially that of the perception of the law governing the phenomenon were never known, and which we employ in the Bell Telephone, and which, fed by naked wires, operated so quietly in causing the undulations of the diaphragm that the slightest articulation, could be the same whilst, bursting all bounds, rushed with the force of a thunderbolt.

When the platinum terminals of a voltaic battery come in contact for a few seconds, or even for a few minutes, the corrosive fumes spurned from them. If the same platinum be put in a pellet, and the same solution, be charged for a few minutes from the patently but powerfully working battery, and put into a glass cell, the platinum will be undissolved by the solution, a large electrical machine of the fricational type, you may hold the pellet in the hand for hours without feeling the electricity that would maintain a continuous stream of fire, and, if you touch the platinum with the tongue, you will not taste it. Moreover, the voltaic cells which decomposed the water in the voltameter so slowly, nor the charge so small, but the smallest measurable space of air; while the chemical effects of the fricational discharge are most violent, more terribly and fast its spark through several inches of air.

M. Plante has devoted the history of the voltaic battery. It was known that by connecting the zinc and the platinum with the terminals of a voltameter, by electricity, M. Achard had little that was new to tell the Institution, and in the summary he stated that transmission of power by ropes furnishes the most economical result, and that where where wide distribution of the power is required, it is the only one to be preferred. As a kind of preface to a description of his system, M. Achard's Archimedean paper will be valuable; but at present there is no data, or at least not sufficient, to enable us to arrive at very definite conclusions. Electricians will naturally hail by electricity, and, so far as we can see, that promises to solve the problem in a very satisfactory manner; but the question belongs to the future, when competitive experiments may have elicited the attention of engineers on the lines which will lead to the greatest amount of success. Electricity has been applied to the transmission of power, and in a few cases has answered admirably; how far it can be economically employed in other cases there are no useful data available in forming the estimate. We know what has been done by Mr. W. Armstrong and by Dr. Siemens, and we look to a continuation in the unsettled country like the United States to supply us with useful information on the subject. In Switzerland water-power is extensively used, but, as we have already established, there is little likelihood that electricity will make experiments with dynamo-electric machines; hence it is only where waterfalls are available that the experiments we want are likely to be made, and only there when a demand for power is created. Manufacturers, as a rule, will not settle in districts where cheap power is the only attraction, and if the cheap power is only transmitted to their premises they will gladly do so. In the course of the discussion which followed the reading of the paper, Mr. Siemens was generally pledged, and some useful suggestions were made which mechanical engineers will keep in mind. Mr. Schönjander mentioned that his attention had been drawn to another means of transmitting power to a distance, by means of steam in properly perforated pipes—a method which is just now talked about in the United States, but which is scarcely within the compass of the question. What is wanted is a successful method of utilising waste power—that of waterfalls, of running rivers,

PACIFIC AMERICAN SUPPLEMENT, No. 839.

The next day it is discharged and then recharged for two hours in the opposite direction, then again in the previous way, and so on. Each time it is recharged and discharged the quantity of electricity present is not found sensibly to increase, but the electromotive force of the battery is found to increase from 2 to 2.5 volts after a succession of actions little by little weaker, and have no longer the power to charge the electrolytic cell, and to discharge through the interior of the lead plates.

The secondary couple is then laid out for twenty-four hours, and at the end of that time is recharged in the opposite direction. It then gives upon discharge as far as this operation that day a fresh alteration in the direction of the primary current.

"Then the interval of rest is extended little by little to a fortnight, one month, two months, etc., and every time the discharge is found ingo on continually increasing. It has, in fact, in the course of nine months reached 1,000 hours. The positive plate, if it is thin, finishes by being almost entirely transformed into peroxide of lead, and is in a very delicate texture; and the negative plate becomes formed by a thick and compact layer of spongy metallic lead, covered with a layer of sulphate of lead.

"It is not always necessary to employ the electric evolution corresponding to the maximum of energy, as for as this operation transformation of the physical and chemical nature of the plates. Thus, one sometimes gains by discharging with a greater resistance and take more time to charge them.

"Sometimes the plates yield a current of sufficient duration for the purposes for which one wants them, it is no longer necessary to recharge them, and one can employ them as primary couples. Thus, for example, the electricity of lead peroxide and spongy lead when the positive plate would indicate a tension of several ounces. A definite direction is therefore adopted, in which the secondary couple is then more powerful, but this is not always charged."

"The plates obtainable—more especially in view of the fact that one can employ them for a time given on, of as to accumulator which will be available for a very long time, and last time to which practically no limit can be put—if possible, to avoid this tedious process of preparation, as briefly described by M. Plante. No doubt it answers the purpose quite well when industrial applications are not to be considered, but practical accumulators, such as must be used in connection with a central system of electric lighting, and which would possibly be required to be set at work at any hour, are very little suitable—more especially in view of the advantages and give to Plante's cells a greater capacity of storage, that I made the experiments that will be described in connection with the modification of Plante's cell, which I used in the Paris Exhibition.

"Here are some of the results obtained in action. The idea of this modification

MARCH 10, 1882.

THE STORAGE OF ENERGY.

LAST week, Prof. W. E. Ayrton delivered a lecture at the London Institution on the "Storage of Energy," which he referred to the various appliances in use for that purpose, but especially to Faure's accumulator. Among the illustrations shown, the lecture-theatre was lighted, in the first instance, by a dynamo for raising heavy weights by means of electric energy which has been stored the previous day in Faure's accumulators, and conveyed to the lecture-room. The total quantity of energy was 50,000,000 foot-pounds—a small thing rather than a large one—as a matter of fact, a small thing indeed, as it refers to matters well understood, and to be compared with the results to which Prof. Ayrton has arrived in the theoretical construction of the Faure battery; and which, when having the plates near together, the latter have a large surface, in order to store much electric energy. And the way to give the plate a large surface, without making it inconveniently large, is to make it of a corrugated form, and to put the two groups half plates near together. Now, Plante made groups had plates that were flat, and were the mere sheets of ordinary lead in sheet acid, and sent a current from cast to the other. This produced, however, peroxide of lead on one plate, and liberated hydrogen at the other. After a while the cell would be exhausted, showing it to only be itself a current through an external circuit. The effect of this was to reduce the peroxide of the spongy lead and to oxidise the other plate, an action which was continued by again sending a current through the cell in the opposite direction to only to have the same action as at first was set. Hence currents were sent out in succession for longer and longer times, the cell being reversed between the sending of each, that is, after long or longer periods, until at length, after some months, when the cell "gave up the ghost," as the old electricians used to phrase it when received, a current is not strong enough to decompose the water, and a return current is produced when the cell discharges.

In 1880 M. Faure thought of the plan of putting a thick layer of red lead on one of the plates, a substance which can easily be reduced to spongy lead by a small charge of a current. Then, after being coated over with red-lead, was then wrapped in flannel, jacket, and the two plates were placed in alternate plan, and the whole rolled together so as to practically form two plates with very large surfaces very near together. To charge this battery the currents are sent somewhat in the same way that Plante's are, but the time is much shorter, and with the exception that the charge is only, and not months, are required in the former case. The battery, when available is reduced to a spongy condition which is gradually lost very slightly oxidised on the other side. It is reduced to the spongy condition on this side by sending a current in the direction of the first, and the last current is on one side. The cell is then ready for discharge, on the other side to an even more extensive action, and so on. Each time there is an extension of the spongy lead, the spongy lead becomes again slightly more oxidised than it was before, and so on until the cell is worn out. A small quantity of oxygen which travels back towards and forms a film of peroxide on the plate. Hence, How does a cell store electricity? No! emphatically no! When a cell is charged so much electricity passes out as passes in, so, when discharging it, just as much electricity passes in as passes out, so that a cell is not a reservoir of electricity, but absorbs energy. The pith then of Faure's discovery was, that instead of using a cell of lead on its inactive oxide, the presence of which layer of lead will oxidise, he reduced it to a fair layer, instead of repelling as much as from the spongy lead is electrically formed out of the oxide, and thus increased the rapidity of passage of electric waves of force.

The next point to consider is—let, the storing capacity of such accumulator; 2nd, its efficiency; 3rd, its durability. Let us take a cell as you have hereby refers to the point, Professor Perry and me to collect a large series of experiments on this subject.

Let us take a single example of the storing capacity. A certain cell, containing 25lb. of lead and red-lead, was charged and then discharged, discharge being eighteen hours—six hours in three successive days; and it was found that the total discharge represented an amount of electric energy equivalent to 1,140,000 foot-pounds of work; energy is the term now in use from-power for time—practice of an hour. 1,140,000 foot-pounds of work stored per pound weight of lead and red-lead. On the second day we made it give out energy more rapidly than on the first, and on the third more rapidly than on the second—of being done, of course, by diminishing the time the current is clients. During the last day we were discharging with a current of about 25 amperes. But in connection with the storing power there is a very curious phenomenon to which I think not much attention has been directed, and that is the loss of the storing power of a Faure's cell. When a cell has been charged and discharged, charged, and is left for a few hours by itself, it appears to have obtained a new charge. For example after the 18 hours' discharge just referred to, although there apparently was an electric energy in the battery cell, it was found that after a few hours' rest on the accumulator small given a current of over 50 amperes, and discharged it down, large flashes of fire. The phenomenon was wonderfully like the invigorating action of sleep. In our case, during our experiments with an extremely rapid and powerful discharge, we found that after several charges and discharges after the cell threw out the same as much energy as it did in the first discharge after charging. This recuperative power has doubtless explained many people who have possibly discharged Faure's cell very rapidly, into under-estimating its storing capacity. Not getting out, after a time, as much energy in the first discharge, they have hastily concluded that a considerable portion of the energy put in was lost. But in fact nothing was wrending there in the cell; the experiments were carried out carefully enough to allow it to come out. This recantilling power may be due to the rest after very short periods of rest, is of great importance when a large amount of energy is required for a short time, as, for example in starting a tramcar after such stoppages, which is common on the horse. Secondly, as regards efficiency. The efficiency of an electric accumulator—that it, the ratio of energy out, take it to the watt given in and discharge on the speed with which it is charged and discharged, or discharged. The latter, of course, is the more important. Thirdly, a certain amount of power will be wasted, or "lost" as the term is, whenever a current passes through a body, some heat is developed, and the greater the current the greater the heat, the latter, however, increasing much more rapidly than the current. Now, it is found that in a Faure's cell not a little energy is wasted in the form of heat, and the greater the current the more rapidly does the current waste by heated discharging. Secondly, it is also possible to find out how much of the energy put into the cell is wasted in heating the cell, and how much is stored up in the cell in chemical disintegration. In the experiments shown first, a certain fixed quantity was, experiments with a current of 17 amperes, the loss in charging and discharging combined, was found to be 40 per cent.; indeed, in some cases, for very slow discharges, we have found it not to exceed 10 per cent. Now, in the Faure's cells, some of the most valuable researches were conducted by Professor Fleeming Jenkin, and published members of Professor Perry and myself, we have found that a current of only 17 amperes can be obtained by discharging a single cell; since, of course, the internal resistance is low; indeed, I shall show you a current of 50 amperes, or about 25 amperes presently. In speaking of the number 17, I merely mean to say that with the current mentioned in the experiments on the efficiency above referred to were made.

We have said that a cell containing 25lb. of lead and red-lead stored 1,140,000 foot-pounds of work. Now, consider what this means. It represents all the energy required to be expended to pull a tramcar containing 40 passengers up a hill 1,000 feet high, supposing the car to weigh 2 tons, and allowing for the electrical arrangements. The electric-motor would have more than about 2000lb. to produce about two horse-power. We have therefore this wonderful combination of a cell which is a source of energy, and all the machinery necessary for over two tons of weight, and 40 passengers with it powered in the tramcar running at 1 or 2 miles an hour, and then after several periods of rest, is capable of recuperation

The dynamo-machine enables us to transform and transmit this energy, and the secondary battery enables us to store the current and utilise it as required in a steady flow of power; but by what means is the tidal energy to be grasped and compelled to turn the armature of the electrical machine. No doubt, as Prof. Thompson says, the accumulator of to-day may become as large as the gasometer of a city gas-works; but we are afraid he advances tremendously when he says that "many months will not elapse" before the fertile atmosphere of the underground railways is replaced by a pleasant and salubrious sanitarium in fragrant ozone!

THE PROBLEM OF THE SCREW PROPELLER.

THE problem of the screw-propeller is one of the few questions which have taxed the highest intellects without being solved, and though for forty years or so it has been a subject of discussion amongst mechanics and engineers, it is no nearer solution, apparently, than it was years ago. And yet the problem is very simple, and apparently so easy: it is nothing more than, What is the best form of propeller for a ship of given size, and with so much engine power? There are some other conditions—such as draught of water, construction of the ship's counter, and many other details—but the main question is easily elucidated. With forty years' experience we should be in a position to state clearly what sort of screw—whether quick or slow pitch—should give the best results in a vessel whose dimensions and engine-power are known; but the fact is, that there are not most intimately acquainted with the subject would be the first to acknowledge that they really know very little about it; they have little more than experience or rule of thumb to guide them, and though to their practice has been fairly successful they would be the last to say that—it was altogether so satisfactory as they could wish. Experiments innumerable have been carried out by the Government, but though so far as the particular ship has been concerned, the best available propeller has ultimately been adopted, no data have been laid down by which a shipbuilder could determine without fear of error, the best possible propeller he could use for a given vessel. In engineering circles, the man who claimed to have discovered the "secret" of the propeller was, and still is, looked upon with recently, however, the perpetual-motion inventor, and it may be that because so little attention has been paid to the views of the enthusiast, nothing, or next to nothing, has been done towards solving the problem. Of late years, however, thanks to severe competition, new lines have had a chance of being practically tried, and some of them builders are not disinclined to get out of the beaten tracks when they see the promise, at least, of improvement. One or two of these novel lines have contained from time to time brief notes of new ideas in screw propulsion, and, on occasion required, more lengthy descriptions; it is for this reason that we draw attention to the somewhat remarkable paper recently read by Mr. J. R. Rost

Cassier's Magazine

FAURE'S SECONDARY BATTERY.

THE following is the substance of a letter addressed to *The Times* over the signature "G. L. R. S." On Monday last, May 9, in Paris, a great battery, or *pile secondaire*, was charged with electricity which was sent from the ordinary Gramme battery in my presence. It may be more economically done, but I was anxious to see the operation. The receptacle consisted of fifty-four lead lattices, each about 12in. diameter and 16in. long, forming a cylindrical leaden vessel, and containing alternate sheets of metallic lead and minium (peroxide of lead) rolled into a spiral united with metallic lead, and the whole placed in a square wooden case. Without any other preparation but lead weighing some 5,000lbs. was packed by a lead weighing some 5,000lbs. was packed by a four wooden cover, through which the ends of the plates loosely protruded, and were followed down for convenience of transport. The lead or "electro" was then put into a bath of dilute sulphuric acid, mixed with the object of rendering it for extraneous matters, and connected to four cubical elements, for which Thomson, F.R.S., at the University of Glasgow, has lately got me to work through the journey from Paris to Dundee (distance increasing a few hours' delay at Calais. I arrived at Glasgow-street at 11 a.m. on Wednesday, after running the gauntlet of customs and police examinations, and was suspiciously looked at, and seemed to doubt my statement that my box only held "condensers for experiments in electricity." The information at the Glasgow terminus of the Midland Railway was also disliked and disobliging. But I was not to lose on the journey I noted the face of the battery charge and found it to have well maintained its full charge from London to Glasgow and Dundee, a number of hours, and finally, in about 72 hours from the time it was charged in Paris, I had the satisfaction of proceeding with William Thomson, M. Faure's care-calling of a "lecture" on the latest and purest battery in existence without that small spherical one cubic foot a power equivalent to nearly one million of foot-pounds! This wonderful box is now deposited in the laboratory of the Glasgow University, and I am told by the able director, and being submitted to a series of tests and measurements, which will be duly reported. But I must, myself, say that I was struck by the simplicity of the whole arrangement, and by the doubtless he himself will give to the public through the proper channels. But I must, myself, say that I was struck by the simplicity of the whole arrangement, and by the absence of any complicated apparatus. The cost of such transcendent importance that the cost per horse-power is certain as its stored force is practically almost infinite as its even bright light. But, whatever may be the practical results obtained, I have the satisfaction of recording that for the first time to my knowledge in the history of the universe has a box of electric energy accurately equivalent to a million of foot-pounds contained within less than a cubic foot of space, latent and potential, been transported from France or elsewhere to Great Britain.

ELECTRICAL ACCUMULATORS, OR SECONDARY BATTERIES.*

By Prof. Oliver J. Lodge, D.Sc.

THE distinction between a primary and a secondary battery lies in so subtle an important one when we are considering either as the producer of electricity, and we may have in our minds a cell with zinc, or, as I prefer, Zn (lambit, just as soon as we consider the working of theoretical reasons.

I shall use the term "element" in preference to "element," as being more general. I define an element, but may also be a compound, such as Zn, Cu, Fe, Ag, Hg, Pb, Sn, Sb, Bi, Au, Pt, Ir, Os, Rh, Ru, Pd, Ni, Co, Mn, Al, Mg, Ca, Sr, Ba, Li, K, Na, Si, B, Ti, Zr, Th, Ce, La, Di, Y, Er, Tb, Cl, Br, I, F, O, S, Se, Te, N, P, As, V, Nb, Ta, W, Mo, U, C, H, and probably others, but so is the group NO, or NO$_2$. A radical is any compound which plays the part of an element in forming combination with another group. Chemists have invented names for many of these radicles into electro-positive and electro-negative, or "basylous" and "chlorous," but these terms have been slow to recognise the full physical meaning of this distinction. They have also, on the other hand, been misused, that, lead, nitrate, and the like, and without entering into the disputed question whether such substances are fixed or variable, it is obviously best to use a definite compound, and when released to call it by its elementary name, whether as an acid, alkali or metal, as the case may be.

It is necessary, however, that radicles can exist temporarily in the free state, when they are said to be *nascent*. Thus when many liquids—as a speak of gases—undergo a number of such dissociated molecules, the molecules are supposed to pass from one to another as well as to the surface of the liquid, and being on the average pretty constant—like the air we breathe—they are equally distributed through the whole

* Condensed slightly from the *Electrician*.

liquid, and if some are left by means removed, more will at once be formed to take their place. Now, if we put any radicle such as NO_3 into a long dissociated—there is, no doubt, a constant tendency—but the average number dissociated at any moment is probably very small.

Now, if we put a metal, such as copper, into a solution which is charged with electricity—half of them with positive and half with negative—the negative ones will, if the metal nascent, a definite reaction—half of them with negative, called therefore electro-negative or chlorous. This is shown by Faraday that the charge possessed by the radicle is constant, though it may differ in sign; and the charge is carried by the latter, the atomic charge, and so on. The resistances of these charges are certain from the facts of electro-chemistry, and the electrical charge appears to be the essential condition for the existence of any radicle or of a free radicle. It further appears that when two opposite radicles combine their charges neutralise one another, and by proximity; and that before two radicles of the same kind can unite into a molecule their charges must be given up to some third body, or body which possesses such dissociated and oppositely charged molecules, remaining about in a *Sea-specific* condition, being decomposed by electrical means, and it is from such a sea that the radicles which have not yet combined to form molecules are not electrolytes, and will not conduct electricity. Electrolytes conduct electricity by a bodily transfer in opposite directions of the charged radicles; they obey Ohm's law of the fact, as a convection current, or rather perhaps of two seas, of dissociated molecules moving in the positive radicles the other of the negative. The resistance of the liquid depends upon the slow clearing away from the sea of radicles by a process chiefly analogous to diffusion, for it is chiefly only assisted or directed by electricity in the immediate—molecular—vicinity of the discharging electrodes.

What now these electrodes? They are conductors introduced into the liquid, with the property of depositing upon the charged radicles in their immediate neighbourhood uncharged, or else opposite, charges. Thus, suppose they are two plates at present connected with a battery, so that one plate is charged with positive and the other with negative electricity. The positive plate will oxygen-electro-positives are attracted by it; they deliver up their charges to it, and uniting into molecules, rise as gas. Their places are taken by others from the slightly more remote regions, and so on, a virtual procession of oxygen atoms continually taking place towards the positive plate, each carrying its charge with it. The same thing happens on the hydrogen side, only that twice as many hydrogen atoms start in the action, the charge of each being only half that of an oxygen atom.

This, then, appears to be the state of things in ordinary electro-chemical decomposition. Gaseous radicles dissipated on the surface of the electrode will combine with it, if in any way possible, instead of merely combining with each other and escaping free. Thus the hydrogen alloys itself as it were with the platinum; and the oxygen, if it finds any copper or other less noble metal on the surface of the electrode, combines with it, and with it, the ordinary chemical affinities being enhanced by the electrical attractions.

But now, instead of two apparently charged plates of the same material, let us immerse in the liquid two plates of zinc and a plate of copper, or any two metals of which have a different affinity for oxygen, and let us connect the copper plate and one of the zinc plates as they were to the positive plate, but apparently by a chemist, not an electrical, force. It may be possible ultimately to reduce chemical forces to electrical ones, or *vice versâ*; but at present it seems necessary to draw a distinction between the attraction for the oxygen in an iodure, only 1·5 volt, and that in a sulphate, which is more than a telescopic distance of the plate. The replenishment of the oxygen into this region is chiefly carried on by diffusion and fresh dissociation. The copper on the other side pulls the oxygen too, but as it is pulled on both sides it does not gain much motion; and very slow assimilation, however, is all that takes place. Hydrogen, on the other hand, appears, provided the plates are not homogeneous, to test the levelling of the negatively charged oxygen atoms, they are equally distributed through the whole liquid, and the charge of electricity to the copper as soon as they are connected by a wire.

The copper so connected, being now negatively charged, attracts the hydrogen atoms, and they are deposited upon it. Now this hydrogen is not ordinary hydrogen. We now therefore have the conditions for an accumulator—namely, the copper plate connected by one wire, and neutralising by their charges the hydrogen atoms on its surface, and the zinc, partially giving up negative electricity to it; the zinc plate connected by another wire, hydrogenising it to some extent, but soon giving up their positive charges to the hydrogen atoms which are present in the liquid. A constant current will therefore flow in flowing along the connecting wire, of negative electricity from the zinc to the copper, or positive from the copper to the zinc.

The electrodes are thus of the same metal, say zinc, but one or both lead, not connected with any battery, but with the two poles of a source of electrical condition—say one coated with hydrogen, the other with oxygen. Plainly the same process of action can go on. The oxygen atoms will be attracting the hydrogen like the copper, or like the zinc, and any charged plate connected with the pole of a battery; the hydrogenised plate will behave like the zinc, and the oxygenised like the copper. The current will flow in the wire from the oxidised plate to the hydrogen-coated one.

We have thus a battery which will maintain a current as long as the plates continue coated or oxidised, and the two gases; but the action of the current is to tend to destroy the coatings and restore the plates to a condition of equality. A battery may be made, then, either of two different metals, or of two plates of the same metal, where the other—the case we will not now further consider because it is not practical—the two metals are connected into the other or one more hydrogenised than the other, by the action of some chemical or other disturbance. Take, for instance, two plates of lead and immerse them in dilute sulphuric acid: but one be bright and metallic, the other rusted over with a coat of oxide of lead. As soon as electric connection is made between the two plates, a current of electricity continually flows along it from the rusted to the bright plate, the bright plate becoming gradually oxidised, and the other becoming gradually reduced. If the plate has been oxidised by exposure to hot air, or by ordinary chemical means, such a battery would be but a primary one; if the coat of oxide has been produced by passing through the cell an electric current from some independent source, then the battery is called a secondary one.

ELECTRICAL ACCUMULATORS OR SECONDARY BATTERIES.*

By Prof. OLIVER J. LODGE, D.Sc.

(Continued from page 37.)

I NOW proceed to the complete investigation of the most advantageous conditions when charging a set of similar secondary batteries with a steam dynamo driven at a constant speed.

Let P be the horse-power actually applied to the driving of the dynamo when it is in full action, at the given speed, as determined by a dynamometer.

Let P' be the power supplied to drive the dynamo at the same speed when it is not allowed to produce any current whatever; that is, the power required to overcome the friction and the resistance of the air, &c. So that $P-P'$ is the whole horse-power available for electrical purposes, and of this some will be expended in heating the armature and field magnet wires.

Let A be the resistance of the armature wire in ohms.

B the resistance of the wire on the field magnets.

R the resistance of the leading wires conveying the current to the cells.

r the resistance of each of the cells.

Let N be equal to the number of cells being charged, and n any fraction which expresses the maximum electromotive force in each cell opposing the charging current in it.

c the current flowing through each cell in parallel.

C the current flowing through the field magnet coil, and C' in the leading wires.

E the difference of potential between the terminals of the dynamo when it is in action charging the cells.

Of three quantities it is essential that E shall be greater than $n\,r$ if the cells are to be charged at all. If $n\,r$ is the greatest they absolutely can be, and if E is equal to $n\,r$, then no current will flow through the dynamo and no charging will be effected. If E is greater than $n\,r$ by a little, and as soon as a current is driven through the dynamo, the engine instead of the engine will begin to drive the engine away at a speed depending on E. If the tuning at the engine of the now driving engine will be in the same direction as when it was charging.

The following relations hold among the above quantities:—

$$E = n\,r + c + n\,R\,r. \qquad \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

$$C = E/B. \qquad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

$$2\,K\,(P-P') = E\,(c+C) + A\,(c+C)^2. \qquad \ldots\ldots (3)$$

$$2 = A\,n\,r + n\,r\,(c+C) + n\,R\,(c+C). \qquad \ldots\ldots (4)$$

The last being a statement that the energy of the motive force generated by the reversed electromotive force of the current flowing round the circuit, is equal to the work that a function is depends upon the construction of the machine, and especially upon how near that machine is to saturation. If it is saturated the function is a constant; if it is nowhere near saturation, the function is proportional. It can be determined by experiment and plotted.

Of all the above quantities,

P has a fixed value determined by the speed required, and unfortunately by cloud-and-sunspots;

n and r may also be taken as fixed and known quantities, for the size of the cell is a matter of convenience, and n is determined by it, while r is a function of the material used in the cells, and for Plasted or Faure cells is fixed.

B is easily altered, and can be made as small as convenient.

A and R are also easily measurable, and though not necessarily constant, may be considered fixed for a particular dynamo.

* From the *Engineer*.

The remaining four of the above quantities, viz., c, C, and E, are dependent variables, and are given in terms of the others by the preceding four equations.

The number of thermal units (water-grammes-degree-centigrade) produced every second is—

$$\text{At the bearings and in the air churned by the machine, } (P-P')\,J.$$

$$\text{in the armature } \frac{A}{J}\,(c+C)^2.$$

$$\text{in the field magnet } \frac{B}{J}\,C^2.$$

$$\text{in the cells } \frac{r}{J}\,N\,c^2.$$

$$\text{in the leading wire } \frac{R}{J}\,(c+C)^2.$$

The energy utilised as chemical work is $N\,n\,r\,c$.

What we want of course is to make this last term as great as possible in comparison with the preceding five terms. Now it gives without saying that the smaller P and R can be got the better. It also appears from the second and third of the above terms that it is good to have A small and B large. Now that about $N^2 \cdot 3$ appears as less easily in the leading wires than in the cells, and hence it must be advantageous to make R small. But then N combines two factors n and r, and the second of these appears second to two of the above less terms; hence, though it is good to have n as great as possible, it is quite a question how big r should be. We find, however, by a little consideration, that r ought to be large as compared with the other terms, that is to make the ratio of useful work to waste a maximum, we must have—

$$\frac{n}{r} = \left(r + \frac{n}{N}\right)$$

$$\frac{A+B}{(p\,(A+B)+2\,A\,B)\,r + B^2\,(A+R)} = \frac{1}{c^2}. \qquad (6)$$

or since R and n, in practice, small, compared with B, we may say that the best possible value of the ratio as nearly as approximately

$$\frac{n}{r} = \frac{B}{c}\sqrt{\left(\frac{A}{r}+\frac{1}{N}\right)} \qquad \ldots\ldots (7)$$

We perceive, therefore, that the best value of n depends upon c. If the current flowing through each cell is very weak, a large number may be advantageously used; but if the current is a great one, then the probable value of r, depends entirely upon c, and n is small, for it is the "tension" or work per unit of current, that is wanted, of current—that is the current per unit surface of the electrodes—which has to be overcome. In a very small current an accident, not only because it is small, but because it is small, more important still, slowly and steadily acting, and so we may give up secondary action; but to overcome a large current of many ampères through the cells there must be, due to secondary actions, and an electromotive force of five ampères would still be very inefficient.

I will therefore suppose that the actual value of r is determined by practical considerations, and is measured by a galvanometer deflection, (p) fixes the best value of n in terms of $n = \text{unity}$, and the value of n'. The equation (6) shows that the best value of c is the maximum permissible value for the current through each cell.

$$\text{Let } c = (1-\alpha)\,A. \qquad \ldots\ldots\ldots\ldots\ldots\ldots (8)$$

But if it is a suitable value, only will the charging be very slow, but, unless the engine is absolutely steady, the value of the rate of the cells becomes helpful to drive it. It need not be so very far short of this upper limit before the current instead of through the same strength only will not be usually great enough to reduce n to n', the minimum value h, new B much below B, and so we may put pretty nearly

$$n' = \frac{E}{r} = A\,n\,r.$$

Or, putting in the last value of c from (8) we get

$$n = \frac{A\,B^2\,(A+R)}{r\,c\,(A+B)+B^2+r\,(A+B)^2}. \qquad (9)$$

The current through the field magnet which enters into this expression is not an arbitrary constant, even at a given speed, since it depends upon how much current is lagged off through the external circuit—that is, upon n'. Nevertheless, the above equation has a properly high resistance, it will be found that c is very nearly independent of n', unless that latter is enormous. And as we have supposed and that n' is nearly very great, we may regard the value of c as the given speed as nearly constant, and may measure it with a galvanometer.

Practically, the value of n would be determined by adding to the series of cells until the current it brought down to the desired small value, taking care that the limit E is not nearly approached, for fear that a disconnection in the speed of the engine might cause it to fall below $n\,r$.

Observe that the greater n is the greater n may be, so as to maintain the most economical ratio (6).

FOURNIER'S ELECTRIC BATTERY.

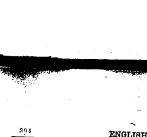
AN alcohol battery possessing some novel features has been recently patented in this country by M. Gen. Fournier, of Paris. The principal novelty is the use of a paste, of consistency of thick cream and glycerine, which is moulded into any suitable form for use as a battery-plate, either in primary or secondary batteries. The patentee claims that he can use either metallic oxides capable of forming, with glycerine a solid compound insoluble in water, or forming the plates, the lead oxide and glycerine are mixed in such proportions as to form a thick paste, sufficiently fluid to be run into moulds. In about twenty-four hours after being thus "cast," the mixture sets into a solid mass which is insoluble in water. This compound is exceedingly conductive, so much so that when immersed in dilute sulphuric acid together with a circuit with metallic zinc, it becomes positive to the metallic state as fast as the zinc is dissolved. It is, therefore, says the patentee, eminently suited for use in galvanic batteries, as it will prevent the electric polarisation, and it will thus either entirely replace carbon or be applied in layers upon carbon, and, as a depolarising agent, it enables one to obtain a simple and rapid battery.

As above mentioned, the compound becomes completely reduced, and, therefore, in the present example we have metallic lead as the product of the reduction, which, being in a complete state of division will be very readily metallised for use again as a depolarising agent, or even become peroxidised, and may then be employed with advantage in the construction of secondary batteries, which may be charged by the direct peroxidised of lead. Or the compound is a compound of lead oxide and glycerine which is not readily reducible, and which will lead to the metallic state.

The oxide of lead in the oxide best suited to form the compound with glycerine, but other matters still better, such as the various galvanic elements, such as the peroxides of lead, manganese, &c., may be employed, although not capable alone of forming solid with glycerine, are nevertheless susceptible of solidification when mixed with glycerine (as above mentioned) with lead oxide and glycerine, and form therewith a solid mass. The addition of peroxides confers greater depolarising properties, and the compound then contains, weight for weight, a higher proportion of oxygen; besides which the peroxides being better conductors of electricity than the oxides, the internal resistance of the battery is notably reduced and its power correspondingly increased. The degree of conductibility necessary to enable the portions of the mixture not already penetrated by the electricity promptly to be the passage of the electric current, and permits of the production of gas at only those points at which the mixture is in contact with the plate, is very suitable for use either in primary or secondary batteries.

Let us consider, first, the action of a primary battery, in which a plate composed of glycerine, lead oxide, and lead peroxide, supplemented as above mentioned, and plunged in a suitable solution of sulphuric acid contained in a cell, forms the negative plate or element, and a copper plate, for example, of suitable thickness forms the positive plate or element. When the circuit is closed, the sulphuric acid attacks the copper plate forming sulphate of copper, and disengaging hydrogen which passes to the plate composed of glycerine, lead oxide, and peroxide; that plate should soon be covered and penetrated more and more by the liquid set in contact with it, and it is capable of very readily oxidising it. The hydrogen which is disengaged at the surface of the plate will act with sufficient energy in reducing as the acid acts on the copper plate, and there results in the compound plate an oxygen to oxidise the hydrogen thereby disengaged.

A battery thus composed is, as to spark, or indefinite duration, as it may be readily reconstituted or reconverted into its primitive elements by the passage of an electric current. Suppose that the whole of the sulphuric acid has combined with the copper and formed sulphate of copper, and the hydrogen thereby disengaged has combined with the oxide of the oxygen of the compound plate of lead oxide, lead peroxide, and glycerine, there will remain



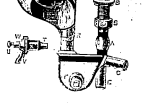


Fig. 327 illustrates the basin properly fitted

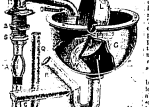

Fig. 328 illustrates the basin properly fitted

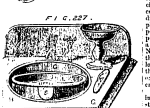

In the battery only the plate of copper partially attacked, sulphate of copper, and the plate of reduced lead. If new an electric current be passed through the battery in the proper way, the sulphate of copper will be decomposed, copper will be deposited on the copper plate, the oxygen of the decomposed sulphate of copper will combine with the reduced lead plate and recalcitrate it, the sulphuric acid will be set free again, and the battery will then be reconstituted and ready for further action.

In the case of secondary batteries the compound plate of oxide, peroxide, and glycerine is immersed in a dilute sulphuric acid solution, in presence either of a sheet of lead, or, better still, a plate composed of lead oxide, metallic lead, peroxide, and glycerine. A current passed through this battery under proper conditions will decompose the water, the oxygen combining with the plate oxide, peroxide, and glycerine, completely peroxidising it, the hydrogen passing to the other plate. Thus we have the elements of a Plantè accumulator, with the difference that the substances employed are in a condition more favourable for oxidation and reduction than steel lead.

ON THE ACTION OF THE MICROPHONE.*

By Prof. JAMES BLYTH, M.A., F.R.S.E.

IN the microphone transmitter, as usually employed in circuit with a battery and a bell telephone, we have essentially two pieces of carbon resting lightly against each other through which the current passes. That the instrument may work with sufficient delicacy it is necessary that the pieces of carbon should be in contact of small sufficient to ensure for the current to pass between them, and, further, that the pieces may not press together so tightly as to prevent any motion of the one sufficiently by the other. The action of light is specifically well described by the term "loose-contact." Now, in order to study the action of this, I endeavoured the action of the microphone, that is the conditions of steadily due to the conditions and arrangements of the parts, I endeavoured to make the action that depends on it loose-contact, and, secondly, the effect produced by tremors set up in the instrument, or wooden supports and connections together, by its sound waves which strike against it and are thereby propagated.

For distinction we may call the first of these the "loose-contact" and the second the "tremor" effect. In experiments I have endeavoured to arrange the instrument so as to isolate these effects, and, so far as possible, examine each of them separately. To isolate the air effect it is obviously necessary either to fix the carbon rigidly in their supports so as to avoid any motion of the one relatively to the other, or to immerse the instrument when these last case in the water that carries it to loose-contact, and, secondly, the effect produced by tremors set up in the instrument, or wooden supports and connections together, by its sound waves which strike against it and are thereby propagated.

For distinction we may call the first of these the "loose-contact" and the second the "tremor" effect. In experiments I have endeavoured to arrange the instrument so as to isolate these effects, and, so far as possible, examine each of them separately. To isolate the air effect it is obviously necessary either to fix the carbon rigidly in their supports so as to avoid any motion of the one relatively to the other, or to immerse the instrument when these last case in the water that carries it to loose-contact, and,

The following experiment illustrates how this may be done.

A, B, and C are three blocked brass finely fixed to a heavy wooden subplate. To the top of A is

soldered a piece of brass tube, B, about 2in. long and 3in. broad. To the top of B is soldered a piece of brass C, about 1in. long and 1in. broad, which is furnished, as marked by the dotted lines, M. A piece of carbonised, C, is fixed firmly into B and has a hole $\frac{1}{16}$in. in diameter drilled through its centre. A long piece of carbon, T, pointed at one end, passes tightly through the tube K and can be moved backwards and forwards by the screw A. A piece of carbon, C, is fixed firmly into B and has a hole $\frac{1}{16}$in. in diameter drilled through its centre. A long piece of carbon, T, pointed at one end, passes tightly through the tube K and can be moved backwards and forwards by the screw A. A piece of carbon, C, is fixed firmly into B and has a hole $\frac{1}{16}$in. in diameter drilled through its centre. A long piece of carbon, T, pointed at one end, passes tightly through the tube K and can be moved backwards and forwards by the screw A.

ELECTRICAL ACCUMULATORS OR SECONDARY BATTERIES.*

By Prof. OLIVER J. LODGE, D.Sc.

(Continued from page 317.)

SO far we have investigated the amount of chemical action in a Faure cell, when a given current is passed through it; but though that is important it is by no means all that we want to know, for there is no reason that exactly will go on in every cell through which the same current is driven, and the chemical work done by a given current on one cell, therefore, mechanically measured, that, of course, the more cells we have in series, the greater the opposing power—or electromotive force—we shall need the current through them; and the electrical energy delivered, then by a given current generator is determined, therefore, by its available electromotive force and by the current's quantity. In this respect chemical work is very similar to the condition of every other form of work, for it is the product of two factors.

Chemical work, as a source of current, a dynamo-machine driven, is subject to Ohm's law (page 7). Of this by being ready to accumulate and drive the current energy magnets and armature, while the other is the resistance, which will cost both of it, and distribute it by power available at a current we have supposed to the air; neither portion is spent in doing the useful work, which is that of maintaining the current through the external circuit. The distinction is real if perhaps upon the power of the generator, and indeed the ratio of the two is called its efficiency. We may, perhaps, premise that a probable value for this ratio is as much as 7, but it is not likely to be more than 9 or 10.

Chemical work, as a source of current, a dynamo-machine driven, is subject to Ohm's law (page 7). Of this by being ready to accumulate and drive the current energy magnets and armature, while the other is the resistance, which will cost both of it, and distribute it by power available at a current we have supposed to the air; neither portion is spent in doing the useful work, which is that of maintaining the current through the external circuit. The distinction is real if perhaps upon the power of the generator, and indeed the ratio of the two is called its efficiency. We may, perhaps, premise that a probable value for this ratio is as much as 7, but it is not likely to be more than 9 or 10.

Consider, as we assume for the present, a constant electromotive force in volts between the terminals of the cell, and a constant resistance in ohms. Suppose, then, that the current is C amperes, which is the chemical equivalent of z grammes per second, multiplied by the number of volts, e, at the same time producing in the whole water-equivalent of w grammes per second, and distributing heat. We will, therefore, take p as a known quantity.

Now N Faure cells and storage them, or to produce such a current, so that they are equivalent to N cells each of a single one. Of these n will be in the condition of cells in work with no connecting wire, and $N - n$ will be in the condition of cells short-circuited if all the leading cables used happen to be taken into account if they are thick enough to be considered as sharing the resistance of the combination of cells in question.

* From the *Engineer*.

To drive a current C of z Amperes through the resistance would require an electromotive force of w volts, which we may call $w e z$, if we put e for the current passing through each of the n series of cells. But this electromotive force is not enough to maintain the current, for more than an infinite; for directly its cells begin to charge, they each exert an opposition force of e volts to the current. This opposition e may or may not vary during charging; but it probably does not vary much, except at the first hour, or so, and it may be measured by readings of the potentiometer between the terminals of a charged cell separately disconnected from the charging circuit. We shall, however, in taking this opposition, or its value will be $n e$, and if the cell is short-circuited it falls off rapidly almost entirely because of the evanescence of the hydrogen plate with the lead. It is in consequence of this that in repeating this charging current, and this it is which we agree to call it volts. The whole set of cells will offer an opposition force $n e$ volts.

If the cells are not uniform we must determine the average e for the n cells, and e, but there is very possible reason for forcing out the cells from the unsatisfactory or uniform ones, and storing them in sets, and afterwards keeping them uniform by subjecting them to precisely similar treatment. It is in practice of maintaining the power of a working battery by occasionally adding an instalment of fresh cells to replace worn-out ones. In this case, unless it is carried on with regularity, a mixture of cells will be produced of very unequal and very different ages, and consequently of very different efficiencies.

Now, as we have only considered in the simplest possible manner the chemical action going on in a Plante or Faure cell, let us consider for a few details of the behaviour it is necessary to know to weigh the actions very closely. In this study we will be greatly assisted by an excellent memoir of Messrs. Gladstone and Tribe, which is to be found in the *Chemical Society Journal* for 1878, in the *Electrician*, 21 and 28 and 30, and doubtless also in other places. A letter of Messrs. A. R. Sims read to the *Society*, February 16th, is also of great interest.

As a preliminary, the reader is recommended to try a few experiments with two simple lead plates, immersed in a tumbler of a finger. Arrange them both behind, and determine them in ordinary dilute sulphuric acid in water. Then, without disturbing anything, pour them for some currently, arranged and which half them slowly and carefully, and a small addition of them to the solution, and note carefully without disarranging the others.

Now connect them with a single Grove cell, and you will see a few minutes bubbles of hydrogen rise from the cathode plate, and oxygen from the anode. Connect with the platinum is already coated with a white crust of $PbSO_4$. In addition to the current will be very much weaker, and no bubbles will be noticed, and presently all action must cease. The discharge current which can be obtained is very nearly weak, as well as for having powerful, or even helpful, to the current. Now the addition of a single Faure cell and connections and notice the direction of the needle, and the direction of the current through it may be kept as low as 5 or 6 milliamperes if it is not to be more than an hour or so. It is quite possible to make r almost wholly negligible compared with e. We shall then get out of the plates somewhat more than the amount of chemical action per second that we passed through, viz.—

$$N = n \frac{76 \rho}{e}$$

$$= 300 \rho \text{ say.}$$

The equations of last week, expressing the chemical total decomposition on both sides of a Faure cell when a given current is passed through it, may be used to express the decomposition produced in a whole set of cells when the proper connections and subject to the utilised home-power p for N hours, by using $\frac{p}{N}$ for the equation $p = 76 \text{ amp} \cdot \text{cm} \cdot \text{cm}$ and $\frac{p}{N}$ for p as before supposed, the number of cells does not signify, for the more cells are used, less will be seen how important this is, and how just the charge with a very low amount of current; hence the more cells charged at once the more economical the process will be. This is why it is usually found to be the most economical when as it usually exist to the highest number of cells simultaneously charged in series, as the current is not to exceed two-fifths of the maximum electromotive force available, expressed in volts. But it may be nearly as great as this with advantage. There seems to be no limit to the number of cells that may be joined up in multiple arc, and apparently the more the better, as the "load" on the armature of the dynamo must be of very low resistance, or they will get heated if as it very often is, they are worked out through such cells in small. Edison's and other armatures seem just the right resistance for some of these machines which are used for electroplating purposes. The wire on the field magnet is short and very large, so as to magnetise them strongly without expending of too strong a current, even though it is thrown with the highest available electromotive force.

The highest available electromotive force is the difference of potential between the terminals of the shunt dynamo when they are disconnected from the external circuit, so that the whole of the current is passing through the armature and round the field magnets. There must be some connection between the two, and this wire on the field magnets, and on the armature, and the number of coils which will give the most economical result, though it is not a question that is decisive to economy-case; but it can no doubt be worked out by a little trial, and I will try next week. Meanwhile let us put in a convenient practical form part of the result of the above activity, viz., that if the best arrangement is adopted in every way, so many being allowed, and the dynamo is driven by electrical motion produced, the total amount of any substance of "atomic weight" w and valency v that can be decomposed or liberated, as the case may be, by p horse-power utilised as current is any time t, is

$$\frac{746 p}{1000 \frac{w}{v}} \cdot t \text{ pounds per hour.}$$

which becomes for Faure cells, where v is 2 volts,

$$\frac{w}{3} \cdot t \text{ pounds per hour.}$$

For instance, 2·8 pounds of litharge can be reconstituted, or also reduced, per hour, by the horse-power supplied to this purpose and to nothing else. The theoretical results are 2·1 p reduced, and 0·7 p peroxidised; that is, 0·3 pounds of solution may be acted on after allowing for the most favourable circumstances. Then, if 5 horse power are utilised as current, 21 lbs. may be acted on per hour, or, say, a ton in 24 hours. To form 120 cells, each containing 2½ lbs. of moistened peroxide of lead, and 2½ lbs. in plates, means 1,440 lbs., which for $p = 5$ gives $T = 288$. But the cells so acted on, of course, will not be fully charged, they will take longer—say, at the very least 360 p hours.

ELECTRICAL ACCUMULATORS, OR SECONDARY BATTERIES.*

By Prof. OLIVER J. LODGE, D.Sc.

(Continued from page 318.)

THE subject of accumulators is very large, we shall find a strong current; we suppose that hydrogenated lead and as much oxygen is one another at first, though the hydrogen is in small, while the size does not. Double the current and you keep half gone already stored with to make the hydrogen of hydrogen adhere better, and even amalgamated it with mercury, but both of it by hydrogen lead, as long as the hydrogen lasts, it is scarcely inferior to a platinum or lead. A current thing, however, it is that even copper opposed to peroxide of lead will be found to convey almost much stronger than when hydrogen is not as strong as hydrogenated lead does. This, of course, is the foundation of Sutton's cell.

All these experiments show the high value of peroxide of lead as the electro-negative element of a cell. Peroxide of manganese is very good, but not quite so good as lead peroxide, which I am impressed by the fact that any of those oxides are not in this way, and it is necessary for them to be in good metallic contact with the electrode, so as to form its real surface.

We can further learn from the first three experiments that if peroxide is not formed on the + plate there is not a considerable evolution of oxygen gas; and then learn convinced that its formation is due to the action of the current.

The action is probably this: first SO_4 liberated against the + plate, some combines with the lead to form $PbSO_4$, but the whole is not thus consumed, for if it is liberated sufficiently fast, and the rest decomposes water, liberating oxygen, and forming free sulphuric acid. Of the oxygen atoms so liberated some combine with the lead to form peroxide, other molecules of oxygen; and perhaps all this oxygen acts. But another part of the SO_4 forms with $PbSO_4$ acts as $PbSO_4 + O + H_2O = PbO_2 + H_2SO_4$, making some more sulphuric acid and also peroxide of lead. Another portion of oxygen may very likely attack the sulphate of lead, and so peroxidise it.

All this is probably quite particular case on. Hydrogen is liberated on the − plate, and it reduces this peroxide. In such cases conducting contact with the lead plate, without first disappearing as $PbSO_4$, but still it is formed by direct solution; that the sulphate of lead itself gets ultimately, though slowly, peroxidised; and sulphate of lead in a non-conductor it can only be acted on by secondary action.

Another experiment of Gladstone and Tribe's is also very instructive. It shows the plates in plain water—or salt it, but as only oxygen gas is given off this is not upon them with twenty Grove's cells, and then surface has stood in the acid a short time before if you like—and then with but two Faures, but only charging, it will heat itself very slightly with $PbSO_4$; but this subsequently does not appear to be easily reduced by the hydrogen, and it is soon full of as a fatal white thing descending current.

Let us now see what is the action of a Faure cell. Suppose it to be fully charged and to have its terminals connected by a wire, so that a current may flow round the circuit. Then, of course, the + plate will be peroxide of lead, and the − plate will be spongy lead. Now, as we have already explained, the current will be very much weaker, and no bubbles will be noticed, and presently all action must cease. The discharge current which can be obtained is very nearly weak, as well as for having powerful, or even helpful, to the current. Now the addition of a single Faure cell and connections and notice the direction of the needle, and the direction of the current through it may be kept as low as 5 or 6 milliamperes if it is not to be more than an hour or so. It is quite possible to make r almost wholly negligible compared with e. We shall then get out of the plates somewhat more than the amount of chemical action per second that we passed through, viz.—

$$N = n \frac{76 \rho}{e}$$

$$= 300 \rho \text{ say.}$$

The equations of last week, expressing the chemical total decomposition on both sides of a Faure cell when a given current is passed through it, may be used to express the decomposition produced in a whole set of cells when the proper connections and subject to the utilised home-power p for N hours, by using $\frac{p}{N}$ for the equation $p = 76 \text{ amp} \cdot \text{cm} \cdot \text{cm}$ and $\frac{p}{N}$ for p as before supposed, the number of cells does not signify, for the more cells are used, less will be seen how important this is, and how just the charge with a very low amount of current; hence the more cells charged at once the more economical the process will be. But the cells so acted on, of course, will not be fully charged, they will take longer—say, at the very least 360 p hours.

IMPROVEMENTS IN SECONDARY BATTERIES.

THE accumulator, or storage-battery, is now recognised as forming an essential portion of many installations of the electric light, especially under conditions where there is a difficulty in keeping the prime mover constantly at work. It is obvious, therefore, that amongst the numerous applications for patents in connection with electric lighting, "improvements" of secondary batteries already form a large percentage. In one for which Mr. R. Kennedy, of Glasgow, obtained provisional protection a plate of clean lead is coated with a layer of lead fluoride or peroxide, and laid in a bath filled with dilute acid. A sheet of lead being suspended over it, current is sent through, and a deposit of close-grained, spongy lead is formed on the lower plate, which can then be cut up to suitable size, and covered with a coat of lead fluoride, obtained by mixing chloride of lime, lead monoxide, and subsequently mixing the product with glycerine. The plates of zinc and lead are then placed in a trough, and the preliminary bath are coated with a solution of lead fluoride in glycerine, lead chloride, and lead sulphate. Messrs. Elwell and Donaldhouse have obtained a patent which covers a number of separate points, viz., cells packed with lead shot, cells filled with hollow balls of lead, which latter are made by coating with lead soluble substance in the form of spheres, and subsequently dissolving out the core; cells filled with cinders, charcoal, coke, asbestos, &c., coated with metallic lead, lead deposited from a salt, such as lead acetate, by means of zinc, lead plates attached to compressed cakes of red lead. Other cakes may be made of lead, obtained by mixing red oxide of lead with litharge or Paris or cement, china clay, powdered glass, and zinc. Fine divided porous lead, obtained by filling a cell having two compartments divided by a porous wall with solution of lead acetate, and reducing the chloride as electrolytes two plates of lead are available, and as soon as the zinc is dissolved it is not replaced by metallic lead, dressing off the exhausted and replacing by undiluted water. In cases where the cells are started with metallic lead plates, oxygen or hydrogen are added to the liquid to assist in the formation of peroxide of lead. In this specification it is stated that porous lead may be obtained direct from lead ore by dissolving it in acid and precipitating the metal by zinc. Another plan has been patented on the Continent by Herr Bröthofer, of Leipzig. In this case a solution of pure red-lead plate of zinc is decomposed by the current, and a thin deposition of lead takes place on the steel star. As an anode this lead foil is employed, after having been previously prepared by folding it lengthways from top to bottom in order to increase its surface. The foil is dipped into an aqueous paste of pure litharge prepared with dilute sulphuric acid, and is coated with a thin layer of caoutchouc. The oxygen coming in contact with the lead foil forces on its surface an exceedingly thin layer of peroxide. By closing the circuit the previously-deposited lead is re-dissolved, and its original sulphate of zinc produced, while the peroxide reduces half a finely-divided lead out of the peroxide, but also a part of the lead plate. By a new regenerative current zinc is again deposited on the zinc plate, while the deposited peroxide is oxidised to peroxide. The peroxidised lead is in said, render the cell ready for use. Yet another invention, which, at least, has some points of novelty, is described in the specification of S. Cohen, of London. In this case the patentee applies to a sheet of lead a layer of mercuric sulphide (HgS) in the form of cinnabar or vermilion. The coated lead sheet is rent into the form of a box or of a spiral, and is used as the positive electrode of the battery. A second sheet is prepared in the same way for the negative electrode. Both sheets are perforated and placed in a cell of dilute sulphuric acid. As soon as the current enters hydrogen is liberated, which reduces the mercuric sulphide, causing a deposition of lead, and leaving a spongy surface of the lead. Immediately the effects of local action are manifested, lead nitrate disappears, thus the oxygen formed, without being destructive to the plate, consequence the water, and in this way local action is always concerned, and invokes backwards and forwards as the cells are charged and discharged, and peroxide of lead is thus formed, the precipitated sulphur uniting as a sublimate. Sulphide of mercury (HgS_2SO_4) may be used in place of mercuric sulphide. These are a few of many patents for secondary batteries, the value of which may be safely said to be an unknown quantity.

THE NEW ELECTRIC LAUNCH.

ALTHOUGH no sufficient particulars are yet available for estimating the actual working cost of the new electrical launch built by Messrs. Yarrow for the Electrical Power and Storage Company, there is much reason to believe that before long electrical launches will become very common on the Thames, if the company can carry their way in erecting the requisite plant for charging the accumulators at several spots on the upper reaches of the river. A steam launch has obvious drawbacks, which we need not specify, and if these who put boats at it in that can only expend upon getting a supply of coils when they require them, even a considerable extra expense in fitting for power will not prevent the rapid introduction of electrical launches. The new launch, which is now on its way to the Vienna Exhibition, is 101 ft. in length, and is driven by a Siemens motor, the spindle of the armature being coupled direct to the propeller shaft. The motor being of the Siemens pattern occupies little space, and is placed under the floor in the stern sheets, the accumulators being arranged across each side, under the seats, and extending from the engine to under the fore. The accumulators are fitted with four trunnions, two for going ahead, and two for astern; a couple of lines leading from each bracket by the side of the steersman enabling him to change the direction of the movement in a moment, while a cylindrical switch enables him to put on the speed energy of 10, 20, or 30 cells, as may be desired, or to stop altogether. The total weight of batteries, dynamo, &c., is about two tons, or very nearly the same as that of a steam launch, boiler, and coals; but the great advantage of using an electrical launch is seen in the fact that the work expended absorbs only a small portion of the power, whereas, in a steam launch of similar power, several attendants at least will be required. The propeller has three blades, 36 in. in diameter, and 42 in. pitch, which revolves at the high velocity of 1,000 revolutions per minute, without causing vibration, and without any noise, except that caused by the water acting on the water, and the peculiar hiss of the commutator and the brushes. On the occasion of her recent public trial the launch, with 21 persons on board, ran from Temple Pier to Hammersmith, with the tide, in 37 minutes, including a slight delay caused by a basket fouling the screw. The distance is not quite six miles, and a watercan can save a good many yards by steering on

RECENT IMPROVEMENTS IN VOLTAIC AND STORAGE BATTERIES.

THE recent development of electric lighting has apparently given an impulse to the production of improvements in, or modifications of, voltaic batteries, some of which are undoubtedly of value; but, for obvious reasons, the attention of inventors seems mainly directed to the construction of storage cells. If we may judge from the claims put forward by the patentees, Messrs. Hyde, of Cumbernauld, a battery recently described by him is better suited to working the electric light than the Bunsen or Grove, the complete but this space, is very economical, and at the same time of great power and permanency. In a carbon-zinc battery, composed of broken coke, graphitised charcoal or other varieties of carbon, either platinised or not, in the carbon cell, and small lumps of amalgamated zinc in the zinc cell, by which means the patentee is able to expose a larger amount of the surface of the chemicals to the chemical action of the fluids in which they are immersed, and give a larger amount of conducting power to the negative element. The zinc is prepared in a commercial form by pouring it, when in a molten condition, into water, and afterwards amalgamating it. As regards the liquids in which the zinc and carbon elements are immersed, the pat-nee has found that it is advisable to modify the ordinary practice, and has found that numerous experiments that some of the best known galvanic batteries, such as the Bunsen, Grove, Daniell and others, would answer the purpose, but convenient for the purpose of domestic lighting, because they were cheap, in case consumption of zinc, and also because there are objections to the use of the carbon cell of nitric acid, as it gives off offensive vapours. With the view of obviating these objections he has obtained very advantageous results by putting in the carbon cell hydrochloric acid, either pure or diluted, with about one-fifth of its volume of water; but its action must be strengthened by the addition of a small quantity, usually not more than from 2 to 10 per cent., of some powerful oxidising agent such as nitrous or nitric acid, sure, regulated by percentages of potash or other containing two or more atoms of oxygen.

In the zinc cell he uses sulphuric or hydrochloric acid diluted in the ordinary way, according to the strength of the zinc cell chemicals of the sulphates of iron, soda, potash, or magnesia, being preferred for the sake of economy, and also because they are not liable to evaporate.

Amongst recent improvements in storage or secondary batteries we make no contribution a novel feature the invention of Mr. D. D. Fitz-Gerald, of Brixton (No. 3481, 1881) in which carbon is employed in conjunction with lead or compounds of lead. The carbon is in the form of fragments, which should be in direct contact with each other at one or more points, whilst the interstices between the fragments are filled with lead in a state of division, or with an oxide of lead, such as red-lead or plumbic peroxide, or with an insoluble salt of lead, such as the sulphate. The carbon fragments may with advantage be in the first place impregnated or coated with lead by immersing them in a solution of a salt of lead that metal such as the acetate, and subsequently reducing the metal either by heating in a current of hydrogen gas, or by means of air or by electrolysis, and the impregnated fragments being in the latter case placed in a solution of a suitable electrolyte—preferably a solution of the acetate or nitrate of lead with which a plate of lead is used as anode. In the construction of a cell or couple with the carbon fragments the latter are divided into two portions, each of which is in contact with a plate of carbon, to which a suitable terminal is attached by the use of a binding-screw or by casting on to the carbon plate a lug or piece of lead in which a connecting or terminal wire is imbedded. The two portions of carbon fragments are prevented from coming into contact by the use of a diaphragm of felt, of unglazed earthenware, of Paris plaster, or other suitable material.

Mr. Fitz-Gerald prefers to employ boxes or vessels of wood rendered waterproof by immersion in melted paraffin, the interior portions being further coated with a waterproofing substance such as marine glue. These boxes, or containing vessels, have two of their dimensions very large in comparison with the other dimensions, so that when an oxide of the box is removed the remaining portion has the form of a square tray. A plate or strip of gas carbon of smaller dimensions than the bottom of the tray is laid flat upon the latter, and is made to project through the side of the tray sufficient to make a link a contact. A layer of carbon fragments of about thickness as nearly to half fill the tray is then laid upon the bottom, and lead in a state of division, such as as cells or leadskin, is laid on the metal is rubbed on to the carbon and shaken down into the interstices between the carbon fragments, and subjected to a pressure sufficient to bring the carbon fragments into good conductive contact with each other and with the carbon contact piece. A plate of porous earthenware, a sheet of felt or other suitable material to constitute a diaphragm, is then laid upon the compressed layer, the edges of the diaphragm being impervious to the tray. Or a layer of Paris plaster may be cast on the layer of carbon fragments, the plaster being used in combination with the felt, or otherwise. Upon the diaphragm is then placed a second layer of carbon fragments with the lead-oxide mixture filled with lead or a compound of that metal, exactly as in the previous case. The fluid of the box constituting a lid or cover to the tray is then fitted with sufficient space to be lying between the carbon fragments and conductive contact. To secure uniformity of action the carbon fragments may be employed, and for this purpose are introduced during the electrolysis a glass tube may be carried into the upper portion of the box or containing vessel. The electrolyte may be dilute sulphuric acid in the proportion of one of acid to ten or twelve of water.

Mr. J. W. Swan, of Newcastle, has also patented further improvements in secondary batteries, in which, after corrugating the plates, as described on p. 61, Vol. XXXIV., he exposes the plates to the combined action of a weak acid, and binds acid, and atmospheric air, which results in an oxidation of the surface of the plates. The plates thus treated are paired with other plates in the combined action of a weak acid, and peroxide of lead

ENGLISH MECHANIC AND WORLD OF SCIENCE:

TESTING BATTERIES OF LOW RESISTANCE.*

THE practical difficulties which are found to exist in carrying out the ordinary battery resistance tests, when these tests are applied to the measurement of batteries or accumulators of low resistance, and the inaccuracies attending the usual method, therefore, of overcoming these difficulties may prove useful. One fruitful source of error is no doubt imperfect connections from the terminals of the various cells not being properly cleaned or screwed up, whilst the resistance of the connecting wires themselves may introduce an error which cannot be neglected when the cells to be tested are in extraordinary small; for instance, the resistance of a single cell of an accumulator may be as low as ·001 ohm, that is about the resistance, of 12 inches of copper wire of No. 13 B.W.G. or 1·10th in. diameter. Supposing, however, that the proper precautions have been taken so as to avoid such errors as the foregoing, a considerable difficulty still remains to be overcome. It is pretty generally known by those who have had to make practical measurements that in order to take battery tests with anything like accuracy, it is necessary that one measurement be made with the battery connected to a resistance coil of exactly equivalent to the resistance of the battery itself; this is known as the "method of equivalent deflection," method we first connect the battery to a galvanometer of very low (and consequently negligible) resistance, and then having noted the deflection, we introduce into the circuit a resistance sufficient to reduce the deflection to that point which is obtained in the current if owing in the circuit has been halved; the value of the resistance or other resistance added in the circuit is the resistance of the battery. Instead of reducing the current to one-half absolutely, it is sufficient to introduce sufficient resistance in the circuit to produce a decided diminution in the deflection, and then from the two deflections so observed, and the resistance added in the circuit, the resistance of the battery can be determined by a simple formula.

Another well-known method is to charge a condenser from the battery, and then to note the discharge; a second discharge is then taken with the battery in circuit, and then the resistance of the battery is determined by a simple formula. Now, in once the two methods just mentioned are correct, it is very necessary that the values of the resistances be decided one. Fortunately, if the first definition of a Thomson's galvanometer, say, be 100 divisions, then the reduced deflection should not be less than 100 divisions, and preferably it should be as near to 100 divisions as possible. Assuming, however, that 150 divisions are obtained, this would mean that the battery is shunted by a resistance of two-thirds times the resistance of the battery. Now, supposing we tried to test a single cell of an accumulator having a resistance of ·001 ohm by this method, then, since the shunted cell should have a current flowing through the latter equal to

$$\frac{2 \text{ volts}}{\cdot 001 + \cdot 0015} = 800 \text{ amperes},$$

a current sufficient to fuse or at least seriously heat (and therefore change the resistance of) a resistance coil, even if the latter were massively constructed, and be only measured in the battery for a very short period of time.

In order to reduce the strength of the current flowing in the circuit, either the resistance in the latter must be increased or the electromotive force must be diminished. By the following simple ex-

* Dr. Hoorn, in the *Electrical Review*.

pedient we can effect the required result:—Take 11 cells, say, of the battery or accumulators to be tested, and divide them in two sets of 6 cells each, and 5 cells each, and then connect the two sets in series, but in such a way that the negative pole of one set is connected to the positive pole of the other set, then by connecting the ends of the two sets oppose one another, the electromotive forces of which correspondingly will be that of 11 cells less that of 5—or 11 cells. Then we have a battery with an electromotive of 11 cells, but with an electromotive force of 1 only. We make a test with such a battery or accumulator, which would have just forfeited, then the shunt which would have just forfeited, then the shunt would have a resistance of $\frac{11 \times \cdot 001}{11 - 5} = \cdot 0018$ ohms, and the current flowing through it would be

$$\frac{2 \text{ volts}}{\cdot 001 + \cdot 0018} = 454 \text{ amperes.}$$

THE DANIELL CELL.

By JOHN T. SPRAGUE.

THIS is the only galvanic battery which gives us an approximately constant current, and has, therefore, many important uses. It is used, however, on account of its generally supposed; but is subject to variation from several causes. These causes call for and repay a careful study, because they illustrate many of the principles of electricity, as well as for their own practical importance.

A battery which would at all times, and under all variations of external work, generate a uniform electromotive force would be invaluable; most of the books indicate that the Daniell does this, and define its electromotive force as being volt. 1·079. Unfortunately, this force is by no means so definite. Let us first clearly understand what we require and mean.

Constant current. When the battery once set up a battery under certain circumstances, giving a certain current, then that current shall be steadily maintained till the materials of the battery are exhausted. This involves several considerations: current depends upon, 1st, the electromotive force; (1) the electromotive force; (2) the resistance of the circuit. Of course, the conditions assume that the external resistance remains unchanged; therefore the constancy, or fluctuation of current, may arise from variations in either the force generated, or in the internal resistance of the battery. As to this latter, there is an inevitable change, due to the formation of the products of decomposition of the cell—namely, that the conductivity is naturally diminished as the fluid in the cell accumulates; the same occurs when the cell is exhausted by absorption of some ingredient of the fluid, but the difference is less because the original fluid is weaker.

Duration is quite distinct from constancy; it depends entirely on the cell containing materials enough to continue working the required length of time; this is, therefore, a question mainly of size of cell, as related to the required work. This is now pretty easily comprehended by aid of my "chemic" unit of current hour, which, by the way, because it requires 1 chemical equivalent in grains of every agent taking part in the work for every 10 hours, and as 3·68 chemics = an ampère current, the calculation is simple for any required conditions. The essential re-action of the Daniell is the substitution of zinc for copper in the sulphate; therefore in any one hour there must be provided a supply of copper sulphate of 120 grains per chemic per 10 hours; or multiplying this by 3·68, we have 72 grains per hour per ampère of good crystallised sulphate, containing 25 per cent. of copper. On this point it should be understood that sulphate of copper is often very impure, iron and zinc replacing the copper, and therefore the salt should be examined.

Of course there will be a loss in heat action corresponding to the consumption of zinc and proportion to the cell does less electric work. Of course, also, it is useless to supply the salt in excess of the quantity of zinc available, and for prolonged working it is necessary to provide for removal of the water arising from the dissolved salt.

The electromotive force of the Daniell is subject to many causes of variation which have been usually slightly neglected. According to the chemical theory, it should correspond to the heat of combination or replacement of copper by zinc, which, according to the determination of Julius Thomsen, is 26,150 calories per gramme atom, agreeing also with the actual heat generated electrically, which he found to be 26,282 calories; three numbers being for the two equivalents, bring out the electromotive force as 1·1863 volt as the theoretical value, using the values formerly received. Dr. Wright, who has examined the subject, using other values, makes this equal to volt 1·185, and his experimental determinations of the force with solutions of acid of different strengths give values.

Sp. gravity of liquids	1·038	= volt 1·123
"	1·060	" 1·133
"	1·070	" 1·142
"	1·176	" 1·163

Sulphate of zinc at the zinc plate has advantages over acid because it does not set up appreciable heat action. I have endeavoured to measure its comparative force; but the various disturbing causes presently to be considered prevented my arriving at any certainty. I believe the force to be the same with sulphate of zinc half saturated and with acid of 1·038, which is one part acid to ten of water by measure.

The difficulty of getting exact measures is at the zinc plate. I find that cutting several strips of zinc from the same sheet, amalgamating them alike and at the same time, they will give forces varying as much as volt ·03. Besides this difficulty, the mere suction of the zinc plate in the liquid will produce a similar amount of fluctuation, though no appreciable effect results from moving the copper plate. This is probably due to the disturbance of the small bubbles of gas which form at all defective points of the plate, and protect it from further action; these being shifted, a fresh action takes place on the zinc, which lowers its available force for the time. Dr. Wright states "in 24 hours I found that but little difference was produced by using pure commercial, or by amalgamated, zinc, or zinc coated with a film of copper." This is entirely different from the received opinions, and very different from my own experiences. I find that amalgamated zinc has the higher force by about ·01, as compared with new sheet-zinc, and more as against corroded zinc, and that the E.M.F. of any zinc plate is always increased by cleaning off the resiliency impurities, and renewing the amalgamation.

The effect of copper deposit on the zinc is very marked, and may be easily tested; if the zinc plate be touched with a copper wire the force falls ·05. This is not, as sometimes said, an effect of *contact* lowering the potential; it is a direct chemical action; there was already a copper contact in the zinc conductor soldered to the zinc; in fact, merely touching with copper out of the liquid produces no effect; the copper must be under the liquid, so that it sets up a local action. I found that by adding a little copper sulphate to the zinc solution, so as to have always copper on the zinc plate, the force fell ·03, when the touching with a copper wire produced no effect. It is evident, therefore, that where a constant E.M.F. is desired, the zinc plate used should not be free from copper. But all loose deposits of copper should be removed at intervals.

Variation of temperature affects the E.M.F. Heat raises the force; it does so by affecting the solubilities of the two salts, and applying externally the energy absorbed in solution. I find that between 32° Fahr. and 52° there is a difference of volt ·01, and between 50° and 60° also ·01, and between 56° and 100° about ·023.

These experiments were carried out by means of cells consisting of U-tubes; the bends of which contained sand mixed with oxide of zinc, to prevent passage of the copper salt. I found these remained in perfect action for a week without a trace of copper passing; the tubes were mounted in stands with mercury cups, and the plates of metal had wires attached, so that they dropped into the cups as the plates were inserted in the tubes, and could be readily exchanged.

The galvanometer used was a reflector of 9,000 ohms resistance. The plan adopted was to oppose two cells and observe the deflection due to any difference in the forces. These deflections were valued by a simple, though only approximate process, which may prove useful to experimenters, as it places at their disposal any desired electromotive force. I connected a large Daniell cell with my resistance instrument of 1,000 ohms arranged in decimal sets. Now, by the law of distribution of potential, this gives a complete range of E.M.F., because any interval at any part of the circuit of, say, 1 ohm furnishes a force of volt ·001, provided we use it against a large resistance. Therefore, by including in the circuit of the experimental cells and galvanometer, different intervals of the resistance instrument, I could add just so much E.M.F. as was necessary to balance the condition which increased that of one of the cells, or value the actual deflections: in this experiment volt ·001 produced a deflection of 100 on the scale. Unfortunately, I had not the means of making the most difficult measurement of the actual force of the Daniell in any given condition, for which different experimenters give values ranging from ·9304 to 1·2, though the figure generally accepted is 1·079.

It is generally conceived that the Daniell is not subject to "polarisation"; that is to say that its E.M.F. is constant whatever the external resistance may be; this is not exactly the case; it is affected by the "density of current" derived from it. According to Dr. Wright, a surface of 12½ sq. centimeters (19·5 sq. inch) will maintain its E.M.F. up to a current of ampère ·001, and will lose 1 per cent. if called on to produce ·005, and 2 per cent. if called on to produce ·01. These figures are, however, entirely special, according to a particular construction. The cause at work is very clear; it is, that the current is exactly in proportion confined to the supply of copper salt presented to the cell, and that the solution is not strong enough to meet the demand, we have copper, not in copper salt, but in sulphuric acid, because the copper has been removed from the molecules adjoining the plate; thiscan only be corrected by the process of diffusion. His battery appears to have been arranged for the experiment in the very worst manner possible, with the copper plate at the top in a weak upper solution, shutting above a denser zinc solution. My object in these experiments was to discover the best arrangement to provide a constant and reliable electro-motive force, such as is needed for experimental purposes, and one which could be set aside ready for use at any time.

M. Gaiffe some time since devised a form for this purpose; it consists of a compound inner cell, the upper part of which is porous; this contains the copper and copper salt. The outer cell contains the zinc in form of a ring at the top of the cell, and a plate or wire of copper at the bottom connected to the ordinary copper pole: the idea is that as the copper salt passes through the porous cell it will sink by its greater gravity, and form a stratum at the bottom when circuit is closed, the resistance between the zinc and the external copper being less than that to the interior of the cell. This outer stratum of copper salt will be first reduced.

I have modified this by making the inner cell consist of a copper cylinder fitted with an upper part of porous earthenware cemented to it, and have also placed the zinc in the inner cylinder. This cell is useful for many purposes, but cannot be relied upon as a steady electromotive force,

MR. EDISON ON STORAGE BATTERIES.

SIMULTANEOUSLY with the publication of the specification of Mr. C. F. Brush, of Cleveland, Ohio, relating to his invention of "Secondary Batteries or Magazines of Electricity," American papers have arrived containing reports of an "interview" with Mr. Edison, in which that gentleman expressed his opinion about storage batteries. Mr. Brush's specification is a formidable affair, as may be judged from the fact that the Patent Office prints it at 2s. 6d. It is illustrated by twenty-one figures, and there are altogether fifty-six "claims," so that those ought to be a good many novel points about the latest invention which the correspondents of the daily papers have taken under their patronage. For the benefit of those who may wish to procure a copy of what must, in one sense, be a remarkable document, we may mention that the No. is 3163, July 1, 1882. To return for the moment, however, to Mr. Edison's opinion, if we may accept the report in a London paper, he did not mince matters, but declared the storage battery to be, in his opinion, a "catchpenny, a scientific humbug, a mechanism for swindling by stock companies." Such expressions do not emanate well from their alleged author, however true they may be, especially when we have further on that in 1879 Mr. Edison himself patented a storage battery and a method of using it in a system, after having rung all the changes on it. His plates were prepared like Plante's, which thought were "dodges to save," are better than some of recent invention. After his first disdainful of scornful criticism we gather from the report that Mr. Edison went into the matter in the usual scientific spirit, and whether he is correct in all his assertions or not, his views ought to be commended to the attention of those who are studying the question from the standpoint of investigators. "Scientifically, storage is all right, but, commercially, as a business, storage is a failure." The ordinary form is (Plante's battery) and he can store electricity, but, as he adds it, but it is gradually lost, and will all go in time." These words express exactly the opinion which have been put forward in this country and in the columns of this paper, but Mr. Edison goes on to explain why the storage battery is a failure commercially. The efficiency which is commonly stated at a very small below that of the current employed to charge the battery, begins to diminish after a certain number of charges, and by-and-by, the capacity also declines. Owing to corrosion of the sustaining plates, the effects of local action, and other causes, the yearly depreciation is, according to Mr. Edison, not less than 50 per cent. of the first cost if used daily, so that in four years, at the outside, a complete outfit of new accumulators will be needed wherever the system of electric energy is adopted for the purpose of lighting a building. In this way, we think, he safely assumes that the storage battery do deteriorate in power with age (whether used or not), but if the latter they are utilised or not); but if the rate of deterioration is anything like that stated by Mr. Edison, the cost of accumulators will be practically prohibitive in any commercial scheme of electric-lighting. A very simple plan is that with a plant of engines and storage batteries, the former could be used during the day to charge the latter, and then during the night both could be used to supply current to the lamps, which is quite feasible; but, then, remembering what has been said above, and the additional fact that the storage batteries will cost about twice as much as the plant which is to store them, it is not difficult to find where the economy can come in. As Mr. Edison puts it, an interpose between the source of the current and the lamps where it is to be used, a "thing in which there is a loss both in charging and discharging, and a loss in standing"—losses which exhibit an increasing ratio as the battery gets older. On pp. 495, 516, it will have been observed that others are aware of the commercial disadvantages of the accumulator; but it may be that in the future some one will discover a means of storing electric energy without waste, or with that minimum amount of waste which would not entirely discount the glorious advantage of the storage battery in the matter of convenience. The storage battery has its legitimate uses, but we suspect that where it is a question of the economical utilisation of energy it will have no place in the system. During the last four or five years, inventions of storage batteries have been almost pouring into the Patent Office, and we have given descriptions of many of the most promising in these columns; but a few months ago rumours began to circulate that Mr. Brush, the inventor of the well-known dynamo, had invented a secondary battery which was superior to anything else of the kind. We did not pay much attention to these rumours, only to procession of "corkscrew" deposits, but also to the arrangements of the elements, and to devices for automatically controlling the current employed in charging the batteries, and for measuring and recording the energy spent in the work. The process of forming the battery adopted by Mr. Brush is based on that of Plantè—that is, he employs lead plates; but he clearly explains wherein the defects of the earlier arrangements lie. The ordinary form of secondary battery lead plates are increased in dimensions subjected and, and when a current is passed through, a coating of peroxide of lead is formed on one of the plates, while the other coalesces the latter coating of the water. The exciting current being withdrawn, the two lead-plates are joined by the chemical work done, a cell, a current flowing between them, but in the opposite direction to the exciting current. The action of the exciting current becomes slower as the coating of the peroxide grows thicker; and if it is withdrawn when a certain coating is completed between the plates, it is found that local action takes place between the coating of peroxide and the metallic lead supporting it, and the former is gradually reduced to a lower oxidation until it becomes unable to yield a secondary current, unless recharged or reoxidised. That explains the loss of charge, and also the high resistance of the plates after long standing, for peroxide of lead loses conducting power with loss of oxygen. The charging must be reversed in order to revive both plates, and this the hydrogen plate may have a greater capacity equal to that of the oxygen plate. Use the combination of the hydrogen and oxygen, when the battery is discharging, forms pure water in the spongy coats of the plates, and that also increases the resistance. Further, the production of a coating of peroxide, and its reduction on discharge, causes the lead plates to unravel electrically a coarse and corrosive surface to the opposite plate, and the result is that in time the coating peels off in parts, while every time that the battery is worked soft plate of lead is formed, which exercises a deleterious influence. According to Mr. Brush, these disadvantages are avoided by the use of three plates, or two plates and a metallic cell. Two plates are so arranged that they receive a coating of peroxide, while the hydrogen plate is placed between them; or the two plates may be put into a lead vessel, and both receive a coating of peroxide, or coating with a layer of oxide of lead, mixed with caustic alkali, instead of the other salts of lead, which are stated to yield non-coherent deposits. Compressed, rolled, and perforated plates are well adapted to retain the coating, but they should be prepared by having the hollow part filled with peroxide of lead, and then compressing them, and then uncovering them horizontally in a bath of caustic soda or potash. When the depressions of one side are properly coated, the plate is reversed, and the other side treated in the same manner. Mr. Brush says that plates of other metals than lead may be used—such as gold or platinum, in which cases the peroxide cannot lose its oxygen by local action. Another method of coating the plates with porous metal is to reduce the lead from the oxide and other salts by a reducing gas at a temperature insufficient to cause fusion. Mr. Brush accomplishes that by placing the plates in a chamber in a horizontal position, charging them with lead oxide or nitrate, and passing through the chamber carbonic oxide mixed with nitrogen. The coating thus produced is said to possess properties differing from those of spongy lead, and from those of the electrical deposit of lead, having many of the advantages of the latter while being free from the disadvantages of the spongy lead. Plates may also be made of metallic lead and the oxide, pressed together into a compact and firmly coherent body, the value of oxide ramifying and extending through it, and forming channels for the passage of the electrical action. Other modifications of forming plates are described by Mr. Brush; but so far as we can see, the disadvantages of the storage battery still remain sufficiently numerous and serious to warrant much of the criticism to which it has been recently subjected by Mr. Edison.

SECONDARY BATTERIES AND THE ELECTRICAL STORAGE OF ENERGY.

THE first of a course of two Cantor lectures on the "Secondary Batteries and Accumulators of Electricity," by Prof. Oliver J. Lodge, M.A., F.R.S., was delivered on Monday evening last. The lecturer said that the subject of storing energy was very numerous, and might be divided into two classes—namely, those in which the energy was stored up by the raising of weights, as by the pumping of water into a reservoir; and that on a very different principle of storing energy for future use, as a force.

Another instance mentioned was by the rolling of springs, or producing strain in them, as in the winding-up of a watch. Any elastically strained body in winding-up watch. A third form of accumulating energy was by charging a Leyden jar. The action of the jar form of a Leyden jar was that it was a chemical action, but that was not the case. Chemical action than is a mere straining of the molecules of the glass vessel. If the glass be strained by pressing it, or by pulling it under the internal tension, producing a disruptive discharge and perforation of the glass vessel. There were the various chemical methods of storing energy. One chemical method was by the process of electrolysis, and other explosives which depended on heat because of that this use of the term chemical energy was somewhat unreasonable in the case of explosives, for in it were combined substances not in a state of equilibrium, which, by a disturbance, rearranged themselves when a light was applied to them. The results of the action of the explosive energy of chemical energy. By the application of heat was produced a material which could be used to do work. Then there was the case of gunpowder, the lead, and a peroxide, but these were not satisfactory for use as plates than either lead peroxide. Its peroxide was less soluble in dilute sulphuric acid than lead peroxide, and hence, when used in plates, gave the largest quantity of electro energy. The action of the cell was that when it was charged by the oxygen which was set free at one of the plates passed into the other plate, and by the act of expression the molecules between that it did; but Dr. Frankland, who was present, said that he had made careful experiments of a somewhat similar character, and considered that it did not. Whatever the explanation might be, the fact remained that the secondary battery was undoubtedly a valuable one. Dr. Frankland thought that it would be signalled by the positive and negative plates, and that the current would be signalled by the negative plate, and that the current would be signalled by the liquid, the lecturer was not able to say whether it was so or not. The cell was then charged with a current, and from which the current was taken, and it was found that the negative plate was signalled by the liquid with the current left. In other words, the cell was signalled by the liquid with the current left. In other words, the cell was signalled by the liquid with the current left. In other words, the cell

themselves. This was devised by Bessa and Sellon almost simultaneously, Sessa being actually the first in point of time. In its perfected battery known as the Faure-Sellon-Volckmar, the lead becomes a grid filled with an extremely composition, which is the peculiarity of the invention, and to obtain the whole process of manufacture, and to exhibit the specimens they now before them of the work in various stages. First of all, cast-iron moulds were procured, stored all over like a grid-iron with a network of straight channels. Two of these mixtures were put together, and the mixture of red lead and acid was put in the moulds, and when about of lead were cast as the result. These framed grids were then filled with compositions—litharge for the positive and sublead for the negative plate, the composition being made into a paste with diluted sulphuric acid, and run in. Though the plates were somewhat dusty, as might be seen, the composition adhered to the lead, and could only be removed by heating the plates hack. The next stage was to form cells. A large number of plates were put together in a trough, all the positives and negatives being kept by themselves, and each plate was separated from the next one by a frame of vulcanite. The dilute sulphuric acid was then poured in, and the cells were nearly all assembled. They gradually became blackened upon the lines of the laminæ, the centres of the holes being the last portions to change colour, and the whole surface was in a spongy condition accessible to the liquid. As they would see from the specimens, a peculiarity about the Faure-Sellon-Volckmar cell was its dark colour. The plates were then stored in Faure cells ready for use, being carefully isolated by the India-rubber inside. Another plan was now being tried by Mr. Thornton of packing out the composition from certain holes and filling them up with the peculiar indestructible plugs; but if the plugs were not put in properly they would be forced out of the holes. The mode of estimation in the liquid was ascertained by an ingenious copper balance and hydrometer. The plates were made in two sizes, the one double the size of the other, and were packed together, also positives and also negatives, in a box. The small sizes of cell were known as the "Volckmar" cells, and the large ones as the "Faure" cells, the term signifying, of course, such a power "per hour," and combinations of cells were manufactured up to five H.P., the only difference being in the number of plates per cell. About 24 negative plates could be set in a small size of plates, and such a pair would discharge a current for six hours at 10 ampères, or for three hours at 20 ampères. The author stated that he had 20 cells at his factory in Liverpool, and he found them almost perfection. He was indeed surprised at the amount of energy contained in them. Having explained the process of charging and discharging the cells, Mr. Lodge mentioned that the reduction of the lead oxide to metallic lead was not carried out in the cells, therefore, that no more sulphate should accumulate than was absolutely necessary. If accumulate more rapidly likewise than in the action. Indeed, if kept in action, these cells were very efficient; but if suffered to be idle, they rapidly deteriorated. Most of the difference found in the cells was due to the unequal density of the mass. The sulphate on the positive plate was less important than that on the negative, because the cells attacked the former far more readily. The chief second of the most economical use of a secondary battery lay in charging them slowly, never filling the cell beyond its capacity, and it never completely if possible, discharging it. Secondary batteries, as well as slowly as possible, although this cannot always be practicable. The electro-motive force in a small cell or half h.p. cell was about 2 to 2½ volts per hour, or about 10 ampères for six or eight hours. By a series of diagrams on the walls, it would be seen that the amount of energy was nearly uniform for to the end of discharge. This was a fact which made a battery realities. It was to be hoped that the small engineers would be able to "very remarkable."

Of the nature, the battery found the somewhat doubted by Professors Ayrton and Perry the best for the purpose, and it was a striking example of the improvements introduced into pure science by the electrical industries. The author gave a formula to determine the internal resistance of a cell—

$$R = \frac{E - e}{C},$$

in which formula R represented the internal resistance, e the current, E the electro-motive force when producing no current, and e the same potential when producing a current. This resistance was extremely small, never exceeding ·002 of an ohm.

TRIBE'S IMPROVEMENTS IN SECONDARY BATTERIES.

On page 913, Vol. XXXVI., we gave description of a negative plate for secondary battteries, the construction of which had been patented by Mr. Alfred Tribe, of Denbigh-road, Bow. That gentleman, it may be remembered, has been engaged with Dr. Globtzow in carrying on an elaborate series of experiments with Crystal accumulators, and their exhibit at the Crystal Palace was amongst the most interesting of the purely scientific branch. Recently Mr. Tribe has obtained a patent for a positive plate, which is constructed as follows: A rectangular frame, preferably grooved, may be employed, having three sides of prepared wood, slate, porcelain, or any non-conducting substance, the fourth side being open to dilute sulphuric acid. The foundation is completed by the use of a sheet of suitable conductor, preferably of lead, the same being cut to project beyond the liquid. The frame may be made entirely of any suitable conductor, such as lead, or it may be made entirely of wood, porcelain, or slate, a suitable conductor (preferably of lead) being placed within the groove and passing round the frame, or nearly so, on three or both sides, either partially or wholly. Into or upon one or other of these frames the positive plates of lead or mixture, or the same in mixture with compounds of lead, such, for example, as the oxides of lead, or the sulphate of lead, or mixtures. The peroxide of lead, or the mixture, may be brought to the desired consistency by the employment, either of water, or, by preference, of dilute sulphuric acid, and, if necessary, the peroxide remains in the retaining frame until the same has consolidated. Or a core consisting of a compressed mixture of lead and mixtures, or the same mixture in a state of paste, may be coated with sulphate of lead. The peroxide may be fitted into the retaining frames, to which is supplied a mixture of a suitable consistency, consisting of peroxide of lead or mixture, or peroxide of lead or mixture in combination with other compounds of lead—such as sulphate of lead, or the oxides of lead, or mixtures of the same in conjunction with water or with dilute sulphuric acid. The element prepared by any one of these methods, and of any convenient shape (which may be other than that mentioned), may be encased by any suitable porous supporting wrapper, such as felt, flannel, calico, asbestos-cloth, or the like, and the plate thus encased is then reduced to the metallic condition, electrolytically as is well understood. When the reduction is practically completed, the current so obtained is then capable of being employed in secondary batteries as positive elements in conjunction with a negative element, such, for example, as that described in the previous specification. The plates may be also established into the circuit of a battery, as the claim in the recent patent is for a positive plate, consisting of lead in combination with a frame of lead, or in combination with a frame of non-conducting material, but with a conductor of lead connected substantially as described. The fact that Mr. Tribe has taken out patents for a form of secondary battery, in which peroxide of lead plays the important part, may be taken as a fairly conclusive evidence that at present nothing better is known, though announcements continue to be made of discoveries or inventions of secondary accumulators, the performances of which are said to be "very remarkable."

loss of liquid need occur; and, as soon as it has been used, it can be removed from the water, wiped, and heated on the plate until the water is completely dissolved. The beaker once more filled with a little water, and removed; the liquid is allowed to evaporate till syrupy, the "syrup" is diluted with its own bulk of hydrochloric acid, and the whole evaporated carefully to complete dryness. After finishing a dozen tests, the dry residue is treated with 5—10cc. of HCl and reduced. Phosphorus and the acid heated until the iron is dissolved. By this process the silicon has been converted into insoluble silica, which, together with any graphite present, is now floating in the liquid. The acid solution is next evaporated somewhat, diluted with rather more than an equal bulk of boiling-hot water, and passed through a small filter-paper into a tall cylindrical precipitating-glass of about 70cc. capacity. This must be done by the filtration will be very slow. The beaker is rinsed with a little hot water, sufficient to wash out all the ferric solution, the ashes which adhere to the beaker being allowed to remain, and the filter is washed with a few fresh lots of hot water till the washings come through colourless. The beaker is then rinsed free from ashes, which may be thrown away, the filtrate and washings containing the oxide of iron, warmed, and a little water added; after the precipitate has thoroughly settled, the clear liquid may be drawn off within five pipette-loads, and the crucible and contents again boiled and weighed. This is not, however, quite right, as the ashes will not be necessary if the ash is taken in washing the pipette.

The dry yellow ammonium phosphomolybdate thus obtained contains 1·63 per cent. of phosphorus; as that its weight × ·0163 represents the weight of phosphorus in the 2 grammes of iron or steel operated upon.

Another Table on the Percentage.—Since the factor of the phosphomolybdate ppt. is regulated by the presence of hydrochloric acid and chloride, these must be removed before the molybdate solution is added. The reason why HCl is added at all is, that if the original nitric acid solution of the iron were evaporated to dryness to separate silica, a residue would be obtained which would contain nitrate of iron, $Fe(NO_3)_3$, and only with great difficulty again is hence HCl is added solely to enable the silica to be separated, and this having been done, it is removed again by repeated evaporation with HNO_3.

In precipitating the phosphomolybdate, it is essential that a *large excess* of molybdate solution be present. In presence of an excess of molybdate solution, no precipitation occurs if the temperature be raised much above 50° C., there is danger of some molybdic acid being precipitated, which would increase the weight of the ppt. The 50cc. is white, and 10cc. of it will fully saturate the pressure is probably the cause. To insure the absence of a ppt. of molybdic acid in the solution, the details of the process should be followed as closely as possible. The presence of a large quantity of ammonium nitrate very much accelerates the production of this ppt.

It is necessary to add plenty of acid, in addition to that which is already present in the molybdate solution. But care must be taken to prove that the ammonium nitrate added does not contain free nitric acid, or a low result will be the consequence.

My own experience leads me to believe that the addition of ammonium nitrate tends to cause the formation of an impure precipitate, and that where the ppt. is weighed direct, it is better to add none. The ppt. is slightly soluble in the 5 per cent. NaCl solution, so that when more than is necessary must be employed. Ammonium chloride, in combination, dries away 2 parts by weight of the ppt. means less than 2 per cent. of the whole ppt. which cannot be washed from the filter paper may safely be neglected.

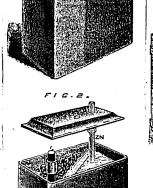
(To be continued.)

SECONDARY BATTERIES AND THE ELECTRICAL SYNDICATES' EXHIBITION.—II.

THIS second and last Conte lecture on this subject was given on Monday evening by Prof. Oliver J. Lodge, M.A., D.Sc., of Liverpool. The first was taken by Mr. W. H. Preece, F.R.S. The lecturer commenced by referring to his own experiments with a little battery on the platform of the theatre, which consisted of only one cell, and which, though very small, was capable of working on the action of secondary batteries. The experiments were then performed, and the possible of lead, it acting better than any other known electrolyte. In the experimental cell he had been using two plates of lead. If he substituted a clean lead plate for one of the lead plates, and put the cell in action, a deposition immediately took place in the peroxide of lead, though whether it was really attached by the dilute sulphuric acid he could not tell. But by substituting for the platinum plate a copper, they would see that the latter metal was more strongly plus, and that its action was more rapid. Copper was therefore a better metal than lead for the plus plate. The copper was oxidised, and formed a sulphate of copper, and as that dissolved the liquid in the glass cell was gradually assuming a blue colour. This would proceed either until the plate could was saturated, and could take up no more copper, or, if the current were reversed, until the whole of the copper was deposited. This was the principle of a Sutton cell, but with the action reversed. As to the quantity of energy which could be stored as lead on the table showed for some time on a piece of falling-off. It was not very clear why the heating cell was not in more general use, although it was probably due to the expense of the metal used or which fills. For small cells, however, a piece of lead answered very well, and he imagined, it would be still better than copper, but they would observe that the action was very slow in a very brief time, and could not be renewed either by real or by washing. Therefore, it was necessary to use a strongly plus metal, and he had found that a lead plate was a good one for the purpose. Dr. Gladstone and Mr. Tribe had said that a thin coat of vermilion was formed on the plate. He would next remove the vermilioned, or positive plate from the cell, and substitute for it a hydrogenised plate, when a very powerful secondary combination, action, would be produced. This hydrogenised plate of lead was therefore, resistance, and the result was that the current was one to sixteen-sixteenths of an ampère, which was of very great value in preventing local action on the plus plate. He would next take a piece of sprung lead which had been heat him just before the lecture. This he had prepared, the same as for the vermilion, and he found that it lasted longer in force, and the electric ball would keep the current up for a short period. Lead could be rendered spongy in various ways—electrically, chemically, or mechanically, and by any of these means the surface exhibitions of the surface exposed to the action of the liquid was greatly increased. Then postponing the period at which the maximum force on its surface required effecting, and enabling it to be used in positive or plus plate. He would, in passing, refer to the great advantages derived from the impurity of lead in its use as a support for the peroxide. They would see that when he took a piece of clean lead and hydrogenised it, then it refused to pass a current after the first minute, and if this were not the case, they would be unable, for a short time, to send a current through the battery, for the lead and its peroxide coat would act as a miniature cell. This they saw if a piece of copper foil was added to the cell, the cause for this peculiarity was that the copper was more plus than lead, and would act on the latter. The reason for this protection was the thin but insoluble coating formed of lead sulphate protected the plate, and would be the life of the cell, for, if it were soluble, a violent local action would set in, and the cell be spoilt. It was known that manganese was not so good as lead. It had been recommended by several of the cells described by various writers, but the cost was considerable and troublesome. Mr. Lodge then described and explained the Sellon-Volckmar cell, which was known. The minus plates could be improved by being hydrogenised, and by rolling the paste. The plan adopted by Wulf, of Liverpool, was to form a thin coating of lead by means of electricity, and then to add the electricity deflected again a bend, from which it was removed by a knife. The Sellon-Volckmar cell was perfected, and in the process of Kodish was used was beat or rolled. A plate eight, again, be coated with salt of lead, which was removed by the blow of a hammer. The plate was then hydrogenised his plate increased with a thick sulphated coat, and was ready for use. He would now call the attention to the glass plates he had tried, he had not found anything better than lead, but Planté cell was second other considerations had to be borne in mind in selecting a battery for practical purposes, such as constancy, repair, and economy of the cells. The lecturer dealt next with the question of electrical energy, and pointed out that the energy of a battery depended upon, as at times they needed to ascertain the current, electro-motive force, and resistance. Ohm, and energy, and of these the first two were known as electrical quantities, and the third as mechanical. For measurement of current, the unit of measurement being ampères; for that of electro-motive force, volts; and for that of resistance, ohms or galvanometers. The quantity equalled the current multiplied by the power equalled the current multiplied by the power equalled the current multiplied by the electro-motive force; and the energy equalled the quantity multiplied by electro-motive force, or the power multiplied by the time. Electro-motive force might be regarded as corresponding to pressure, resistance to friction, and the result of a given amount of work was done. The quantity (a current x time) was measured by a Joule's meter, and the power by a Watt meter, or by means of the galvanometer. It seems best to use the Siemens' dynamometer for the purpose, as at times they needed to ascertain the current, electro-motive force, and resistance of the cell, and energy, and of these the first two were known as electrical quantities, and the third as mechanical. For measurement of current, the unit of measurement being ampères; for that of electro-motive force, volts; and for that of resistance, ohms or galvanometers. The quantity equalled the current multiplied by the power equalled the current multiplied by the electro-motive force; and the energy equalled the quantity multiplied by electro-motive force, or the power multiplied by the time. Electro-motive force might be regarded as corresponding to pressure, resistance to friction, and the result of a given amount of work was done. The quantity (a current x time) was measured by a Joule's meter, and the power by a Watt meter, or by means of the galvanometer. It seems best to use the Siemens' dynamometer for the purpose, as at times they needed to ascertain the current, electro-motive force, and resistance of a cell and the amount of energy it could store and give out. The latter could be found by using or failing of that beam of the balance which was connected with the armature, and the quantity of work done by this means was found by multiplying the current by the distance and the change and discharge of a cell, and hence the percentage of return and loss. Cue gramme decomposed or dissolved equalled 1·9 ampère hours, and power was measured

THE INSULITE SEALED CELL.

THE British Insulite Company, Limited, with three holes, into two of which the electrodes have recently brought out a useful form fit water and air-tight, by the aid of collars of battery cell constructed of their special formed of pieces of rubber tubing; while the compound, and have also fitted it with a well fitted a closed by a stopper and capsule, forming and connections in a manner which will com- a release-valve to provide for the slight ment itself to the attention of all who can variations in the pressure of the contained appreciate the advantage of having an elec- air. When the capsule is screwed home, tric cell which can be arranged to communicate the cell may be shaken about or inverted between, say, the sitting-room and the kitchen, in a without injury or escape of the liquid; few minutes. The illustrations show the Insulite and one turn of the capsule is sufficient to leave the cell in a permanently working condition. The Insulite lid, having been fitted to the electrodes, is pressed down on the diaphragm, and outrageously soldered in position, the zinc being inserted about two turns with the average amount of sealing-wax cement, and being readily replaced when worn out. The diaphragm is made by nickel-plated cups, split and held by pinching screws to the carbon and zinc rods, and as the latter are tightly surrounded by rubber, there is little risk of defective connections from corrosion or other effects. As will be seen in



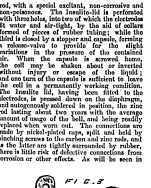


Fig. 3, the magnets and hammer are all covered by the bell, and the whole arrangement is as neat and portable as can be desired. It commends itself at a glance to all who want an electric bell which can be fitted up practically at a moment's notice. The cells are of such a shape that a battery of them occupies the minimum of space (see Fig. 1), and they will doubtless be found in many places where cells of other kinds would not be tolerated nuisances. The E M F of a single cell is said to be about 1·6 volt, with an internal resistance of 1·5 ohm. For portable electric bells they appear to be just what was wanted, while in the battery form they will be found very useful for testing purposes where the lineman has to carry his battery out of the way anywhere where a rail can be driven, as, when in such position that their capacity is afforded the cell for performing its duty. Insulite is a material which apparently is excellently adapted for the formation of cells, as it is exceptionally free from impervious to oxidation, and is self-contained, so to speak technically, it can be outgenerously used. In Fig. 2 the cell is shown ready charged, with the lid fitted. It is an oblong vessel, on plan, with a diaphragm of porous material securely secured in opposite corners, thus dividing the cell into two equal compartments. In one there is a carbon rod surrounded by fragments of carbon about the size, and in the other the familiar zinc-

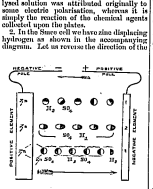
SECONDARY BATTERIES.

By JOHN T. SPRAGUE.

THERE requirement of science was based upon the natural fact that most operations are reversible: a falling weight will drive clock-work, and the clock-work will raise the weight. So in chemical action oxygen and hydrogen combine and give up energy while forming water, and an equal quantity of energy applied as an electric current decomposes the water (unburns it, in fact) and separates the gases. In this action the energy connected to one equivalent H 1 grain, O 8 = water 9, is measurable as 0,806lb.-ft., and the electric conditions represent an E M F of 1·5 volt. In like manner every chemical action which, giving up energy, constitutes a battery or electric generator, can be reversed by means of a superior E M F, when it receives and stores up energy. Such batteries are therefore called *accumulators*; they are also called *polarisation batteries* because the E M F found to exist upon pairs of plates in an electrolysed solution was attributed originally to some electric polarisation, whereas it is simply the reaction of the chemical agents collected upon the plates.

2. In the Smee cell we have zinc displacing hydrogen as shown in the accompanying diagram. Let us reverse the direction of this



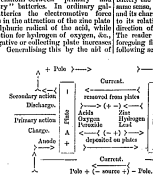
force, as shown by the arrows, adding also a molecule of water H_2O which is to be decomposed; then we have $ZnSO_4 + H_2O$, which becomes changed into $ZnO + SO_4H_2$. O: the zinc is separated, sulphuric acid formed, and oxygen set free, provided there is nothing for it to unite with.

3. In the Daniell cell we have zinc displacing copper from its sulphate, $CuSO_4 + Zn$ becoming $ZnSO_4 + Cu$, with generation of an E M F of 1·07 volt. Applying the same superior force we can reverse this process, and by electrolysis of the sulphate from a copper anode convert it into copper sulphate and deposit zinc. Here a Daniell cell, when exhausted, can have a reverse current from a dynamo-machine passed through it, and be fresh charged. This is one of the forms of "accumulators" which has been proposed, but it is not practicable for reasons which will be explained hereafter.

4. Reverting to the conditions of § 2, we have oxygen freed, and this is wasted energy; it may be saved by collecting the oxygen and using a plate in such a manner as to form a gas battery which will gradually absorb the oxygen; or we may use a plate of such material as will absorb the oxygen chemically; such an electrode exists in the ordinary manganese cell, or Leclanché battery, for the exhausted sesqui-oxide of manganese will take up the oxygen again and reform the peroxide. Iron, or oxide of iron, will also act in this manner, and Lead is, however, found most suitable, because in the presence of sulphuric acid, lead does not pass into solution from the anode, but forms peroxide, and this being a good conductor constitutes a very powerful negative element or battery plate.

5. Zinc, in the presence of acids or alkalies or of most metallic salts, sets up spontaneous action; therefore, the next step towards an ideal accumulator is to substitute some metal not so acted upon; palladium has the property of absorbing 900 times its volume of hydrogen, forming with it a true alloy, in which hydrogen apparently becomes a perfect solid metal, and conducts electricity; but for the cost of palladium this would be a valuable electrode. Experiment has shown that lead is the best available metal, and we then come to two plates of lead, with a solution of sulphuric acid between them, in which the decomposition of water is produced by electrolysis, the oxygen forming peroxide of lead, while the hydrogen is partly occluded in the porous lead surface, and partly employed in reducing pure lead from previously formed compounds.

6. A slight sketch may now be useful in fixing in the mind the principles involved and the relations between "primary" and "secondary" batteries. In ordinary galvanic batteries the electromotive force originates in the chemical action of the zinc plate for the sulphuric radical of the acid, while the attraction for hydrogen of oxygen, &c., at the negative or collecting plate increases the force. Generalising this by the aid of

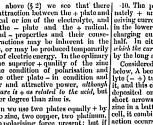


the figure above (§ 2) we see that there exists an attraction between the + plate and the – radical or ion of the electrolyte, and between the – plate and the + radical. These + and – properties and their consequent attractions may be inherent in the substances, or may be produced temporarily by means of electric energy. In the ordinary battery the superior + quality of the zinc sets up the condition of polarisation and attracts the other plate – in condition and polar order and attractive power, *although its ion undergoes a + relation to the acid*, but + in a lower degree than zinc is.

7. If then we use two plates equally + by means of two zincs, two copper, two platinum, we have no polarising force present: but if by any means we can set up differential attractions at the plates, the force comes into existence. If we insert an electric source in the external circuit, we polarise the two plates in opposite directions, and give them this differential attraction for the ions of the electrolyte, to an extent depending on the E M F available; that is to the difference of potential we can set up between the plates. Again, if we modify the plates themselves by coating them with different substances the same effect is produced. If one of the platinum plates is lifted and exposed to the air, its attraction for hydrogen is increased by the film of oxygen absorbed.

8. If we pass an electric current through the two platinum plates in acid, we coat the plates, one with a film of hydrogen, and the other with a film of oxygen; these two films now become the active agents, and their attraction for each other, resulting across the chain of intermediate molecules of the electrolyte, sets up the electric polarisation. Precisely the same result follows from the pressure at the two plates of any other substances having affinity for each other, a condition necessarily set up by any action of electrolytic decomposition. Thus with lead plates, the hydrogen reduces any oxide and is partially occluded in the lead, producing a + plate of lead or hydrogen representing the zinc of the ordinary battery; the oxygen produces peroxide of lead, representing the silver and acid of the Grove, or other powerful oxidant.

9. It is important, at this stage to avoid some probable confusion about *poles* and *plates*, the more especially because Dr. O. Lodge, in his valuable series of articles on accumulators in *The Engineer*, which have appeared in these pages, has contributed to this confusion by using the term + *plate* for that connected to the + pole of the source while charging, and which becomes the + pole of the battery when discharging. But to obtain a clear idea of the relations of the secondary and primary battery the name terms must be used in the same sense, and the word *plate* in the battery and its characters as + or – refers exclusively to its relations to the electrolyte, and to direction of the current *within the battery*. The reader should therefore refer to the foregoing figure, and compare it with the following scheme of arrangement.



10. The plates A B are shown as alternately + and –, according as they are receiving electricity from the source, as shown in the lower half of the diagram, or discharging currents, as shown in the upper half. In either case that *plate is + from which the current passes to the liquid* as shown by the long arrows at the ends of the plate.

Considered as charging from the source, below, A becomes +, therefore the electrolyte (– +) turns its negative ions towards it, and this class of radicals or ions is either liberated on the plate, as shown by the short arrows, or if the plate is soluble, as zinc is a battery or copper in a depositing cell, it combines with these ions. The precipitation occurs at the + plate B where the + radicals subjoining it are deposited.

Considering as discharging, B becomes the + plate by virtue of the presence there of the + ions which attract the – ions of the electrolyte, the conditions being now those of the ordinary battery.

11. "It should be observed that if such a cell is connected to the source, and an external circuit is also connected just as shown, the plate A becomes a constant + *pole* to this external circuit; but a very complicated set of conditions would arise. In fact, the cell and the outer circuit would be derived circuits to the source, and it would depend upon relative forces and resistances what

THE BRUSH STORAGE BATTERIES.

The New System to be Introduced within the Next Three Weeks.

The citizens of the Brush Incandescent Illuminating Company announce that Mr. Brush is now ready to manufacture storage batteries at the rate of seventy a day, the works in Cleveland, Ohio, being finished. For the last six months work has been going on upon the new buildings, which are intended solely for the manufacture of batteries and are supplied with engines of 2,000 horse power. Mr. Brush says that he has greatly improved his batteries since the exhibition of their power which was given last autumn, and now has no hesitation in competing with gas or any system of electric lighting. He became convinced years ago that the arc light, while well suited to street illumination, would not do for dwelling houses or even for many public buildings. The light is too trying to the eyes and casts too black shadows to be pleasant indoors. The incandescent light is as soft as that of gas and does not affect the atmosphere. For reasons of economy it was decided that any system which would permit of incandescent and arc lighting from the same machines and wires was to be aimed at, and the storage battery was settled upon as the best device for building the electricity for each house. The great advantage of the storage battery is that no matter how irregular the charging of the battery may be, its emission of electricity is perfectly steady; no matter how a cistern may have been filled, the flow of water from its faucet will be perfectly regular. The great trouble in feeding incandescent lamps directly from a dynamo machine is that the light shows every variation in the running of the engine; every time the belt seem passes over the fly-wheel a tremor in the light shows it; when the engine runs faster or slower, it is perceptible at once. The current used for the arc lights would never do for incandescent lighting, owing to its irregularity, but it is just as good for charging a battery as any other current. The plan of the Brush company is therefore to put batteries into every cellar and connect them with the street wires which feed the street lamps.

The company is making four standard sizes of battery—five lights, ten lights, twenty lights, and forty lights. The smallest size will occupy the space of a small trunk, and the size of the batteries increase in proportion to their power. They can be put in any part of the house, from cellar to garret, or in the vaults under the sidewalks. The current in the batteries will supply the number of lamps they are intended for for five hours. Thus, a twenty-light battery will supply twenty lamps for five hours, or ten lamps for ten hours. A meter registers the flow of electricity through the battery, and also acts as an automatic cut-off when the battery is fully charged. Mr. Brush contends that the batteries will improve with age; but whether they do or not will be the company's affair, for none will be sold. They will be put in houses and the lamps supplied without charge. The cost of the light, according to Mr. Brush, will not be more than that of gas, at which price it is expected to put in batteries as fast as they can be made. The light needed by an ordinary four-story house, twenty-five feet wide, does not average in winter fifteen lights for five hours.

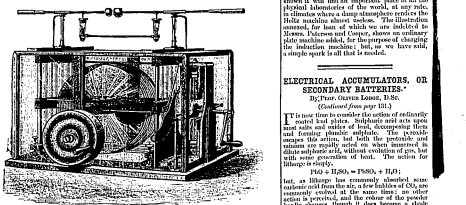
Contracts for lighting by this system have been made with a number of persons, and the batteries are promised within the next three weeks. Among other places, the Central National Bank, some of the stores along Broadway, and the Madison Square Theatre have been wired by the company for the new light, and are now awaiting their batteries. At the Madison Square Theatre it was said yesterday that not only would the light be better, especially in summer, as it gave out no heat, and did not consume the oxygen of the air, but it promised to be twenty-five per cent. cheaper than gas. The Boston factory of the company is now turning out Swan lamps at the rate of 10,000 a week. As there is no work to be done in the streets to introduce this system of lighting, there is no reason why the work should not proceed rapidly after the batteries are received. From the same batteries power can also be taken for running small motors for sewing-machines, lathes, etc. The whole system of batteries, lamps, and motors can be seen by any one interested in the matter at the company's offices, No. 863 Broadway, where they have been in operation all winter.

It is well known that upon the appearance of the first Brush storage batteries suitable of the company's offers, suits will be instituted for infringement of the Sellon lamp patent, and of the Faure battery patent, and that the most eminent expert and patent lawyer of precedence in this country is ranged upon one side or the other in the coming contest, which promises to be the most important ever fought over patent rights.

and have a surplus to propel the machine at the speed aimed at. A velocipede with a 48l. wheel must make 150 revolutions per minute to cover a mile, and if that is to be accomplished in three minutes, when it is to be propelled on its tires in a straight line, it is impossible to carry an engine of heavy weight, a motor running at high speed must be used, and the power be transmitted from the crank-shaft of the engine to the driving-axle by means of gearing.

WIMSHURST'S INDUCTION ELECTRICAL MACHINE.

ALTHOUGH the development of the electrophorus has proceeded steadily with the advance of scientific knowledge, it has scarcely kept pace with the development of machines for producing current, at all events in recent years. We have, however, had an opportunity of examining an electrostatic induction machine which is certainly much in advance of anything of the kind previously known. The method of developing electricity by the inductive action of a body previously electrified was known and utilised previous to the commencement of the present century; but although several designs had been brought forward it was not until Holtz introduced his well-known machine in 1865 that such machines were known to the subject. The Holtz machine and its variations (see p. 327, Vol. XXIII.; p. 344, Vol. XXV.; p. 129, Vol. XXXIII.) are all difficult to make and troublesome when made, for in a moist state of the atmosphere it is only by a great deal of labour they can be made to work at all. The Bottsch machine, which consists of an ebonite disc mounted in front of an electrified plate of the same material, is in that respect an improvement on the Holtz, but it is far less powerful. Carré's dilatateur machine is a combination of the older and newer forms, an ebonite disc revolving to the extent of about one-third of its surface in front of a plate provided with felt friction rubbers and turning in the opposite direction to the ebonite disc. Both plates are thus electrified, and the electricity is collected by means of metal combs. This machine is very powerful, but is somewhat troublesome to start, and requires a considerable amount of power to drive it. Wimshurst's machine, which consists of an ebonite disc mounted in front of an electrified plate of the same material, is in that respect an improvement on the Holtz, but it is far less powerful. Carré's dilatateur machine is a combination of the older and newer forms, an ebonite disc revolving to the extent of about one-third of its surface in front of a plate provided with felt friction rubbers and turning in the opposite direction to the ebonite disc. Both plates are thus electrified, and the electricity is collected by means of metal combs. This machine is very powerful, but is somewhat troublesome to start, and requires a considerable amount of power to drive it. Wimshurst's machine, which consists of an ebonite disc mounted in front of an electrified plate of the same material, is in that respect an improvement on the Holtz, but it is far less powerful. Carré's dilatateur machine is a combination of the older and newer forms, an ebonite disc revolving to the extent of about one-third of its surface in front of a plate provided with felt friction rubbers and turning in the opposite direction to the ebonite disc. Both plates are thus electrified, and the electricity is collected by means of metal combs. This machine is very powerful, but is somewhat troublesome to start, and requires a considerable amount of power to drive it. Wimshurst's machine, which consists of an ebonite disc mounted in front of an electrified plate of the same material, is in that respect an improvement on the Holtz, but it is far less powerful. Carré's dilatateur machine is a combination of the older and newer forms, an ebonite disc revolving to the extent of about one-third of its surface in front of a plate provided with felt friction rubbers and turning in the opposite direction to the ebonite disc. Both plates are thus electrified, and the electricity is collected by means of metal combs. This machine is very powerful, but is somewhat troublesome to start, and requires a considerable amount of power to drive it.



(p. 116, Vol. XXX.). To obtain successful results with these machines, a comparatively high speed is necessary, and, with the exception of Carré's, a damp atmosphere is productive of a great degree of vexation to the experimenter. The Voss machine, the latest invention of the kind that is well-known, which was illustrated and described on p. 345, Vol. XXXIII., has the reputation of being indifferent to the state of the atmosphere, but its power is limited by the difficulty of multiplying the number of plates. Mr. James Wimshurst, a member of the constructive staff of the Board of Trade, has recently introduced a machine which possesses all the power of the Holtz, if not more, with the great advantage that it is practically indifferent to the state of the atmosphere; and further, can be made at a comparatively low cost. Many of the most useful scientific apparatus now have come to us in advance science, and the time is not far distant when the name of Wimshurst will be as widely known as that of Holtz. A few machine on his plan have been already made by Messrs. Paterson and Cooper, of Little Britain; but that constructed by himself is probably the most powerful electrostatic induction machine in existence. It consists of 12 circular plates of common window-glass, 20in. in diameter, which run between 24 strips of similar glass, supported in such a manner that the discs rotate freely between them. Twelve of the glass strips rest on bearers at the bottom line of the discs, and the other twelve are supported a little above the centres, leaving room for the passage of the spindle on which the discs are mounted. There is thus little friction of a mechanical nature, except that of the spindle in the bearings, and this is reduced to a minimum by including in these apertures pads of the great merit of Mr. Wimshurst's invention is found. In the first place they are made up of many plates of graphitic oxide in the armatures on the same side, and there is consequently great loss of effect from neutralisation; but Mr. Wimshurst prevents that by connecting all the armatures on one side by a copper wire, which leads to a conductor, and thus forms a handy means of imparting the initial charge to the machine—a small spark sufficing for the purpose, when the machine is properly insulated. At a comparatively slow speed the large machine we saw gave long handles of spark discharge in the open air between knobs separated by 2in. and more, and when small condensers were hung on the terminals a shock nearly equal to that obtainable from a Leyden jar of 3,000 cubic inches. Turning the hand wheel of the winch at a slow rate, the machine gave from four to five sparks of three inches in length for each revolution, the line of fire being solid and apparently continuous. Such an experiment is sufficient evidence of the power of the machine, which is a decided advance, and one upon which Mr. Wimshurst, the inventor, is to be congratulated. It is not the least merit of the machine that any ordinary person can construct one for himself at very moderate outlay; and as economy becomes known it will win an important place in all the physical laboratories of the world, at any rate, in climates where a damp atmosphere renders the Holtz machine almost useless. The idea of the machine is not new, as Mr. Wimshurst admits, Nicholson, Bennet, and Cooper, shew an ordinary plate machine added, for the purpose of charging Leyden jars, the machine; but, as we have said, a simple spark is all that is needed.

ELECTRICAL ACCUMULATORS, OR SECONDARY BATTERIES.*

By Prof. Oliver Lodge, D.Sc.

(Continued from page 131.)

IT is now time to consider the action of ordinarily coated lead plates. Sulphuric acid acts upon lead salts and oxides of lead, decomposing them and forming plumbic sulphate. The peroxide escapes readily from the acid, but the protoxide and sesquioxide are rapidly acted on when immersed in dilute sulphuric acid, without evolution of gas, but with some generation of heat. The action for litharge is simply,

$$PbO + H_2SO_4 = PbSO_4 + H_2O;$$

but, as litharge has commonly absorbed some carbonic acid from the air, a few bubbles of CO_2 are commonly evolved at the same time; no other action is perceived, and the colour of the powder hardly changes, though it does become a whole lighter. The reaction for minium is not quite so simple—it is this,

$$Pb_3O_4 + 2H_2SO_4 = 2PbSO_4 + 2H_2O + PbO_2.$$

No adulteration of carbonate is commonly met with in minium, and accordingly no gas is evolved, but the formation of black peroxide makes itself manifest by a rapid darkening of the

* From the *Engineer*.

ELECTRICAL ACCUMULATORS OR SECONDARY BATTERIES.*

By Prof. Gaston Planté.

(*Continued from p. 154.*)

THE coatings of both plates being now fully formed, the one all peroxide, the other all metallic lead, the gas which is liberated against their surfaces is no longer absorbed, but begins to rise in numerous bubbles from both the same as from the oxidising plate. A new battery the first few times it is charged, and discharged, does not work well. The fulness of the cell can therefore be told in these two ways—a greater escape of gas and a higher opposition electro-motive force than usual.

The proper or "classic" resistance of the cell is now a minimum, however, for these reasons—because the oxidising surface, the fixed surface of the positive plate, and the free lead, which are as near as they can possibly be, have their acid in the solution in concentrated not in dilute state, that which has been absorbed by the lead having been restored; and because the cell will have been warmed by the charging current. The cell is therefore in all respects at its very best, and if left to itself will remain powerful current for a few seconds if called upon.

But suppose it is not called upon for a current, but simply allowed to stand idle for a time, what will happen to it? First, of course, it will cool, and thereby slightly increase its resistance; but more important than this, the gas which is clinging in minute bubbles to the surface of the plates will act in bubbles and gradually rise, thus lowering the electro-motive force of the cell somewhat. The gas which now escapes is chiefly, as the reader knows, a large quantity of hydrogen with enough half charged with the latter, more especially perhaps if it is amalgamated, and accordingly the hydrogen escapes through it in its abnormal state, retains a perfectly satisfactory rate.

No further change of importance can be expected to be noticed after the lapse of several months or even an hour; but if the cell is set aside for a day or two a more serious change sets in. The first surface of the lead loses some of its hydrogen which has been absorbed slowly by acid, a slight case of insulating sulphate being produced; and these changes, though perceptible, are not of a serious character, but if the plates were insulated, yet no circuitously wandering (Whereby

* From the *Explosa*.

do occur, because they lower the electro-motive force and increase the internal resistance at the same time. The cell, with and supported by a plate of unoxidised lead, and the peroxide sufficiently for a considerable time, and I can say that I have stood there in my quantity for a week or so, provided there is no leakage between its terminals. I advertised, however, that a temporary short-circuiting of the full cell before setting aside, which, though not necessary as far as the other purposes, would have a decided effect in slowly diminishing the store of hydrogen; and that the insulated would not bear standing like quite as well as a perfectly full one.

The main part of the change which occurs during standing seems to take place at the + plate. Here the plate, oxidised to peroxide, with and supported by a plate of unoxidised lead, and the peroxide sufficiently to allow sense of the latter to be perceptible, owing to the position of the two substances, when there is here a complete battery, and accordingly a certain amount of local action sets in, some of the lead becoming oxidised and sulphated, while some of the peroxide is partially reduced. If this action goes on to any great extent it is most disastrous, for the effect is to establish a layer of insulating film or layer, of sulphate and lower oxide, between the lead plate and the rest of the peroxide mass, and it may sometimes happen that the coating is thus completely detached from the plate so as to leave it quite bare, but suppose it only gets detached in patches, the internal resistance will thus be increased, and the current which will be obtained shared by the total amount so reduced; but the electro-motive force would not be likely to be much affected, the effect of the local action had extended itself through the whole thickness of the peroxide. After this it is probably would so reduced by more standing than any current having been demanded from the cell.

Messrs. Gladstone and Tribe have called attention to this local action, and pointed out one reason why it goes on more slowly than might at first sight be expected, viz., that the film or crust of sulphate formed on the lead protects it from the insulating power, and only permits deeper parts to be attacked in by reason of its porosity. Another reason why the action is not at all rapid is that the surrounding mass really permits a very inconsiderable amount of circulation in the liquid, in that it soon becomes saturated with the acid, and is only slowly diminished by diffusion. Still, the local action does go on more or less rapidly, and it is clear that, however, the main cause of the loss of power of the cell while standing. Moreover, the differences noticed among different cells seem to depend very greatly on the facilities which some seem to offer to this action, and to the consequent greater or less confinement of the peroxide coating. Why the coating should be more or some cases more readily than in others is by no means clear; but it may happen that a too rapid evolution of gas caused by a too powerful charging current, might mechanically effect a separation between the plate and its coatings. It must be remembered, however, that the coatings may easily become electrically dead, not by actually detaching film—especially in patches—but by other mechanical influences may remain almost unimpaired.

The naturally occurring cure for these evils would be either to support the peroxide on carbon, or other such unattackable substance, or else to use no support at all, but to make the plate wholly of peroxide, but though the use of carbon would do away with the action, scarcely any form of carbon can resist the action of nascent oxygen, and accordingly in various counties described in passing, and the powder makes a worse battery than the oxidised plate, and therefore connection between the plate and its coatings; in fact, the coatings are liable in time simply to drop off. The use of peroxide alone lacks support, but when the cell is discharged and the peroxide reduced to lead, it will no longer be a conductor, and it does not appear probable that such a cell could ever be discharged to any extent, however, the difficulties of making developed permanent contact with such non-metallic substances are considerable, and their use would therefore be very inconvenient.

SECONDARY BATTERIES.

CHLORINATED batteries, or rather patents for them, are becoming somewhat numerous of late. Still, however, and the number of known combinations is very large, the practical commercial value of these is practical would would not occupy much space. Probably descriptions of secondary batteries already in type would not occupy many volumes, but certainly a new list of them recently taken out for modifications of the Planté cell would occupy a column or two. There is must be confessed a family likeness to one very nearly all of them, and it may be safely surmised that the Patent Office will stop the chief benefit from a pecuniary point of view. One of the most recently patented, and one of promising devices is that known as the B.T.R. cell, from the names of the patentees, J. S. Bremner, W. Taylor, and T. King, of Cannon-street, E.C. This invention relates to the formation of plates for electrodes, made of insulating lapse the materials in combination with suitable metal ribbons; also of insulating tapes covered with metal, or in combination with metal ribbons, gauze, wire, or strips, or to used as to form a carrier for which the material of lead, or lead in a finely divided condition, such insulating carrier being sandwiched, as a rule, between the metallized ribbons, or their substitutes. The insulating carrier and metal ribbons may be made in any convenient manner, and may be corrugated longitudinally and transversely. The insulating strips are coated with the powdered lead, lead material on one side, and with salts of lead on the other. Part of the insulating also relates to plates formed as above, and used in combination with an improved cell made of wood sealed, consisting of with pitch, lined with a cell of paper, treated with paraffin, and having a layer of paraffin interposed between the wood and paper cell. Sometimes an extra particle and of sheet iron is used outside of the wooden one, with an inch-paced layer of paraffin wax. Part of the invention further relates, in combination with glass tumblers, or vessels of them, to a mode of connecting the different sets of plates together, so that any one plate may be easily removed, and the combination of a lock attachment for connecting the cells together, together with an improved tube for ventilating the cells; also in combination with the above improved plates, part of the invention relates to an improved mode of applying sticks, rods, tubes, or strips of active matter or in combination with glass, porcelain, vulcanite, or of metal or wood covered with non-conducting materials. The invention refers, in combination with the above improved cell, to the use of an insulated tray or stand supporting the cell, and for holding all to prevent return current by earth. The claims in this case are for the construction substantially as described. Another device, which, however, proceeded no further than provisional protection, is that of Dr. Aron, of Berlin, in which the accumulation consists in impregnating capillary substances with a lead combination, and winding them into the polar plates. The capillary substances may be fibres stitched on lead plates, and subsequently impregnated with the active compounds, and the polar plates may be of disfigured substances perforated with numerous holes, being of wood, silver, or other metal. Another patent is one by C. T. Kingzett, London, and relates to the form of the electrodes, as well as to the compounds used. The patentee prefers electrodes of a brush-like form, in which the "bristles" are hollow, and with the "stock" are in one piece, which is inserted into the lead compounds. From practical investigations the patentee concludes that while red-lead may be usefully employed at the electrode at which oxygen is set free during the charging process, it may be preplaced with advantages at the other pole, by the sulphate, chloride, or oxychloride of lead; or, better still, a freshly-prepared mixture of litharge and dilute sulphuric acid. Hydrochloric acid may be used as an electrolyte, and it is preferred to charge the cells in one direction only. The patentee refers to chloric hypochloride, as an agent for prolonging or revivifying the action of secondary batteries, and for exciting free access of the electrolyte fluid to the various parts, more particularly to those of tubular-pipes, wicks of porous material, and a "Leclanché" cell, E. T. Wade, 46, Lombard-street, strikes out a new line, for in this case the electrodes are made of carbon and zinc, and half chromium and iron, or "other suitable metals;" the zinc are covered with a layer of an oxide of manganese, occasionally mixed with a little chloride acid, and retained in position by a covering of asbestos fabric, woven open glass, or a portion of the porous earthenware. Chromic acid other than these zincs were to immersed in the fluid and probable of chromium are produced by the action of nearly zinc, and the current gradually charging current. The patentee says that peroxide, until, at the end of five and three-quarter manganic acid as a permanganate and solution of hours, it has reached its maximum, and is an excmanganese, or an oxide of copper may be used polisent caused. The result shows that each with suitable electrodes, instead of the oxides of battery practically involved 5.8-p. deer, the chromium. M. Sonrier, of Brussels, has also consumption of zinc being 1,563 grammes, obtained a patent, one part of which relates to a 2,000 grammes, and sulphuric method of applying moisture to lead plates by acid 7,200 grammes. The 5-p.-hour is means of a thin sheet of wood, or other suitable recoiling it with some equidistributive substance. Another part describes a porte made of minium, ally obtained with the consumption nickel, as a substitute for the usual sheets of lead. The in- estimate of 4 grammes of zinc per ampère-hour, ventor of the 5-and-10 battery, and the B. Hospitalier stated that the battery of electric porcelain absorbing the acid, the latter being ex- motive power, would suffice to support for five hours in tray. M. Sonrier also uses a light and porous the lamp having carbons a full third of an inch cake, the interstices of which are filled with lead, in diameter, with a current of seven amperes, by first soaking in a solution of the nitrate, and a difference of potential of 40 volts at the reviving the metal by heat, and then pressing terminals of the arc. No attempt was made to minium, or other suitable metallic preparation, reduce the weight of the two batteries employed, into the pores. That object is effected in other which was 1480lb.; but, according to M. Hospitaways—e.g., by mixing the paste with aluminium lier, it would be easy to construct two batteries powder, which is said to be oxidised by the sul- of equal power to weigh not more than 1040lb., phuric acid, and by adding the aluminium in such a manner as to considerably less than an accumulator capable of that while the metal is obtained in the desired containing an equal amount of energy. state, the block is kept as porous as possible. Such are a few of the recent ideas in connection with the formation of secondary batteries; but it may be doubted whether any of them are better than the simple Planté form, when that has been brought into its best working condition.

GROUVE'S NEW BICHROMATE BATTERY.

A TEST of M. Trouvé's new bichromate battery has been made by M. Hospitalier with two sets of six cells each. The cells are of closable, and are arranged in a box or trough in such a manner that they can be easily removed —one side of the trough being hinged so that the cells can be slid out when the plates are drawn out of the solution. The elements are connected in series, the zinc of one cell being coupled to the two carbons of the next, and a winch and ratchet enables the plates to be wound up out of the solution, or to be immersed more or less deeply. The electric cells are much larger than is absolutely necessary, and the quantity of solution required for the charge is therefore large. Hospitalier's solution was made up as follows:—Bichromate of potash 1½ kilog., and sulphuric acid 2·8 kilogs., that is 12 oz., 2 lbs., and very nearly 6lb. respectively. This gives 130 grammes of bichromate per litre of water, or 8·5oz. to 1·7o pint, say, 8·5oz. to 1½ pint, a solution half as strong again as that used by Paggenhoff. But M. Trouvé uses a much stronger solution on certain occasions, from 200 to 250 grammes of bichromate of potash being dissolved in each litre of water. The standard solution is 1 kilogramme bichromate, 1 do. sulphuric acid, and 1 pint of water. The bichromate of potash is powdered and added to the water, and stirred; then the sulphuric acid is poured in very slowly through a fine strainer, the mixture heating slowly and gradually. The bichromate, once dissolved, remains in solution, and the preparation occupies altogether about ten minutes. The zincs are fixed to a rod of wooden strips, and would be enfeebled in the injury of the solution. The total weight of a battery of six cells is said to be 39·3 kilogs., say 74lb. In the experiments made by M.

example in the form of powder, may be placed into or upon the existing frame, and subjected to pressure. The peroxide of lead may be employed in a plastic or a moistened condition, either with water or with dilute sulphuric acid. Or one or other of the non-conducting lead compounds—such, for example, as the monoxide of lead, or the sulphate of lead—may be mixed with peroxide of lead, and be subjected to pressure in the existing frames, and there be converted into a peroxide of lead by electrolytic action; or a core of compressed peroxide of lead may be put into the centre of the existing frame, and covered with some suitable lead compound, which may be then converted into peroxide of lead by electrolytic action. The negative element, when prepared, may be sheathed or inclosed in artificial or vegetable parchment, felt, porous earthenware, or other equivalent materials.

When the negative plates, composed of peroxide of lead, are employed in secondary batteries, the positive plates employed therewith may be of any suitable element, and the exciting liquids or electrolytes may be similar to those now employed in secondary batteries.

Mr. W. R. Bevis, of Cinderford, patents a method of constructing secondary batteries of a thin strip of lead, folded up with a band of paper, cardboard, or other such slips with red-lead. The porous material may be asbestos, felt, spongy indiarubber, or wood. The cells are poured into chambers, bags, or closed vessels, in which hold fits sulphuric and diluted sugar-water, and holes are punched through from each side roughly, the barrel edge and the bulging on the punched edge serving to keep the red-lead within the envelope, and its metallic contact with the lead walls, which are thus rendered more rigid.

A greater departure has been made by M. de Lalande, who, in conjunction with M. G. Chaperon, of the Mines d'Aiwaz, Spain, has patented a new battery, in which oxide of copper is the depolarising agent. The negative element is formed of a rod of zinc cut often in a porous cell packed with pieces of carbons, the interstices filled with a mixture of copper. The positive element is of zinc, in a solution of caustic soda or potash. This combination is extended for use as a primary battery, but it may be employed as a secondary. Mr. Brush, of Cleveland, Ohio, has obtained an American patent for a secondary battery, in which the plates are formed with projections for the oxide of lead, which is compressed after filling.

From these notices it will be understood that recent improvements follow rather the endeavour to hit upon the best shape to work up the lead and its peroxide into convenient forms, than to discover other combinations more efficient and less troublesome, if more costly, than the recent designs. Meantime, it is worthy of note that in a recent case the simple Plantè is preferred, probably because there are no royalties to pay.

ANIMAL PARTNERSHIPS.

AN intimate connexion subsisting between different animals is that known as Commensalism; commensalism may exist between any two animals, which may be said to sit at the same table, or to live in the same room or stable. Of late years naturalists have become acquainted with numerous examples of this form of animal partnership, and in the recently issued volume of the "Transactions and Proceedings of the New Zealand Institute" Mr. Hutton discusses the question as to whether the Australian Native Bear, or Koala, is to be considered as a commensal animal. Mr. Hutton says that in a little [illegible] of the Koala [illegible] the roof has been [illegible] a few [illegible] caterpillars [illegible] the Koala [illegible] leaves of the [illegible] and like a [illegible] colouring [illegible] back of its [illegible] afforded to [illegible] On removing [illegible] Mr. Hutton [illegible] specimens [illegible] its hitherto [illegible] leave [illegible] of a living [illegible] however, [illegible] has been [illegible] the world [illegible] have a while [illegible] life to the [illegible] tion has [illegible] sight on the [illegible] whether [illegible] be ever seen [illegible] Koala without [illegible] detached [illegible] stances, it [illegible] seems to [illegible] fishermen [illegible] for fishing [illegible] bird is attached [illegible] turtle, and [illegible] numerous [illegible] crocodile, [illegible] they leave [illegible] with many [illegible] the large [illegible] other dead [illegible] fish-leaves [illegible] swimming [illegible] these point [illegible] selling to [illegible] number of [illegible] fish, and [illegible] tentacles, [illegible] fishes. SECONDARY BATTERIES WITH LEAD PLATES.

It is well known that M. Gaston Plantè "forms" the plates of his secondary battery by oxidising one electrode and reducing the other to a divided state, which permits the chemical actions during charge and discharge to go on more completely. That electrician has recently been studying these chemical actions, and finds that part of the peroxide of lead is transformed into sulphate of lead by the sulphuric acid in the water about the plates. This result has likewise been confirmed by Messrs. Gladstone and Tribe. He has also attempted to increase the accumulating power of the battery by procuring a galvanic deposit of lead on the plates in the first place. But these galvanic deposits would not adhere sufficiently well to the plates, and he has arrived at the conclusion that the best plan is to transform the metal of one electrode into peroxide nearly through and through, and to reduced lead on the other. This has been accomplished by changing the direction of the primary current at intervals with periods of rest between. By this method of preparing the cells, M. Plantè states that it will be possible to obtain a discharge current sufficient to deposit about 74 grammes of copper (1150 grains) per kilogramme (2·2 lb.) of accumulator battery. The system of charging the battery in contrary directions, reduces the lead on one plate and oxidises the other to a corresponding depth, so that during the subsequent discharge the hydrogen from the decomposed water in the battery reduces the peroxide of lead formed by the primary current, and the oxygen oxidises an equivalent quantity of lead. The efficacy of the period of repose between the opposing currents is explained by M. Plantè on the ground that at the end of a certain time the plates of lead thus modified have become less good conductors on their surfaces, and hence the primary current, when it starts again, naturally follows the path of least resistance and enters the liquid at the metal surface under the film of oxide, and not by the surface of the oxide itself, thus outlining a new thickness of metal, and superposes the oxide already formed. A cell thus formed preserves its charge for months. The formation takes a considerable time but it may be hastened by heating the liquid bathing the plates. This is, however, a process requiring trouble, and M. Plantè has substituted the following plan. The plates are left for twenty-four or forty-eight hours in a bath of nitric acid diluted with half its volume of water. They are then washed and placed in the sulphuric acid bath ($\frac{1}{10}$ acid to $\frac{9}{10}$ water) and submitted to the action of the primary current. The action of the nitric acid is evidently to corrode the surface of the plates and give a better surface to the oxidation by the current. Secondary currents thus treated give in eight days after three or four changes of the primary current, discharges of long duration, whilst those made without the preliminary bath of nitric acid only give the same results after several months of operation. The new process thus renders M. Plantè's electrical cell of far more practical value than it has hitherto been.

ELECTRICAL ACCUMULATORS, OR SECONDARY BATTERIES.*

By Prof. Gaston Lucie, D.Sc.

(Continued from p. 61, Vol. XXXV.)

IN the last article I described a few typically important forms of cells which could be made with two clean lead plates immersed in dilute sulphuric acid, and connected at pleasure with a battery, galvanometer or bells. Before going on to the subject of coated plates, it may be well to draw attention to the consequences which a series of observations on plain plates will bring home to the experimenter.

If the surface of the plates are in the ordinary dull condition, he will find, on supplying two fresh cells to them through a galvanometer, that the charging current at first is considerably stronger than it is after a few seconds. He will notice that oxygen rises from the + plate before any hydrogen from the – plate, and that as soon as both gases are freely given off the charging current is considerably weakened. He can also, by reversing the electromotive force of the cell in this condition in very little below that due to two Grenets; it is, I believe, about 2 volts. If the plates are brightened up just before insertion in the acid, the charging current will be weak from the beginning, and oxygen will at once be given off. The strange phenomenon which is observed when the cell is left to itself once more is due to the absorption of the first-formed hydrogen by a coat of oxide on the – plate; and if for this plate we use a purposely oxidised piece of lead, the absorption of hydrogen, and the consequent small production of it during charging current, will continue for some time. The explanation of this is that the oxide of lead in contact with the + plate if it ordinarily coated itself with an absorbent of oxygen; but as this is not the case, no particular effect is noted when the surface is varied, unless, indeed, it be purposely coated with some oxidisable substance. To some extent nitrites and nitrates act both as oxidisable substances and depolarisers, but the latter are the more important and that the most under normal a current through two lead plates coated with litharge or minium than through two plates without any coating at all. The electromotive force of two thrown, which is almost compensated by two clean plates, is amply sufficient to send a strong charging current through two plates coated with red lead, until the coatings are both acted on, the gases no longer absorbed, and the cell full. As this state of things is approached the electromotive force of the cell gradually rises in a very decided manner.

With regard to the effect of amalgamating either or both of the lead plates with mercury, my experiments lead me to conclude that a mercurialised surface of a plate is worse than useless. A coat of oxide of mercury, whether it be left on the plate for a day or long as it adheres, and any rate does not much obstruct the action of the peroxide of lead; but there is a certain point in the discharge when this coat falls off in a sheet, carrying with it apparently whatever peroxide of lead is present too, for the discharge current suddenly falls to zero wherever the plate has been mercurialised. This is a curious observation, but the fact still remains that mercury is unsufficient, and therefore useless. Amalgamation of the – plate does, however, appear to help the occlusion of hydrogen, and is therefore so for advantageous.

The experiment of Professor Herschel, detailed in the last article, is repeated with a modification. Instead of using a plate of the coarse kind produced by a piece of cable that lead as the – plate, and a piece neatly coated with peroxide as the + plate; the current is very weak, and hardly able to ring a bell. But it will be found on careful inspection that this feebleness of current is only arrived at after a second or two; the current at first is much more of a quite strong. The real cause of the feeble current is the formation on the surface of sulphate or peroxide of lead, which forms on the clean lead plate the instant it is used to produce a current, and effectually screens it from the liquid. It causes, in fact, a sudden increase in the internal resistance of the cell. This can be proved in a very simple manner, by observing that the lead plate so treated does not absorb hydrogen with the same ease when opposed to hydrogen-coated lead, zinc, or anything. Wiping removes the film, and restores the full power to the cell. Allowing the plate to remain in the acid for some time also removes the film to some extent, but slowly. As long as any hydrogen is absorbed, and the lead it appears to sustain unlimited current; and the lead is unchanged, but as soon as the lead itself

* From the *Engineer*.

causes such as plod of water. After fixing, soak in three or six changes of water, and then transfer to a solution of acetate of lead. Again wash and dry into prints: then study each well.

FAURE BATTERIES AS A SPECULATION.

PUBLIC notice has once more been attracted to the Faure secondary battery for the economical storage of electricity, by the recent curious transactions between the English Company formed to work M. Faure's patents, and the notorious financier who appears to control the development of this remarkable speculation. It was recorded in last week's JOURNAL that the English Company who had addressed themselves to the work of manufacturing these accumulators had been constrained to alter their policy, at the bidding of M. Philipart, in favour of a mere Stock Exchange procedure. Instead of trying to make a business in accumulators batteries, the Company are therefore committed, by this last move, to the doubtful work of launching licenses or concessionary companies, looking for profit to the premiums to be extracted from these dastiful efforts. The true reasons for this sudden change of front are not given in the report of the meeting of shareholders at which it was consummated. The Chairman of the Company admitted, in as many words, that the alteration was against his wishes, and contrary to the opinions of the Board; but as M. Philipart had the majority of votes in his own hands, his demand was perforce complied with. Something was said at the time about a friendly action between the Company and another joint-stock undertaking, also subject to M. Philipart's influence, who were described as the owners of an accumulator which is the only possible rival of the Faure battery. It is by no means clear, however, how the interests of either scheme can be advanced by proposal to abandon manufacture and stop all sales while a process of improvement is carried on. Ordinary people, not likely to see the magic that still seems to cling to matters electrical, will be disposed to consider that this proceeding on the part of M. Philipart and his friends is intended to mask something else which was not desired to be known. Applying the common principles of trade to the circumstances, as they have been laid before the public, it does not require powers of deep perception, or a mind warped by prejudice, to conclude that the main reason for this change is that the old work of the Company did not pay, and has consequently been abandoned for a movement which is expected at least to reassure shareholders as to the safety of their capital. If the Faure Company could have made a reasonable profit, and could have looked forward with confidence to an unlimited business in the future, it is strongly suspected that M. Philipart is known to be, would not have been content to let matters go on steadily. The very reverse of indifference must have been at work to cause the abandonment of an undertaking that has only been recently launched at great cost, much of which has been expended in preliminaries that have now been rendered abortive. As it is only right to suppose that the enterprise of making accumulators was not a philanthropic venture, but a business undertaking for profit, we are justified in arguing that to relinquish it implies that its main object has not been attained.

There will show whether a great discovery of M. Faure, as it has been popularly regarded, whereby electricity was rendered able to shut up in a box, like Jack-in-the-box's genii in his turn, is now to be consigned to the limbo of failures. It is not so very long ago that the sanguine spirit of Sir William Thomson led him to indulge in those vivid descriptions of the best of energy which was sent from Paris to Glasgow, that afterwards turned out to be the beginning of the second great modern electrical *furore*. The production of this electric lighting by the dynamo machine actuated by steam power the consumer make his own gas. The result of this backward-lead at this time became an old story, and the occasional failures on the part of the Faure Company is to confirm the impression of the lighting were known to be inevitable so long as the work that was done in a hand-to-mouth manner from engine to lamp. If of the earliest experimental stage, and consequently not fit to be was felt that something analogous to the pasboilers of the older system of lighting, or the accumulator of the hydraulic press, was also necessary for electric distribution. At this juncture Sir William Thomson wrote the famous letter in which M. Faure's arrangement was introduced to the public; and when those supply, force, sometimes uncontrollably; the anode plates disintegrate only drawback of electric lighting had been removed. A name and so on. The accumulator is indeed no more a box of the hydraulic accumulator were paralleled at last.

The recent proceedings of the Faure Company, taken in connexion with the unaccountable delay in the business development of the system of electric storage by the Faure or Sellon-Volckmar system, will help to convince the general public—what many to be an electrical apparatus. "Indeed," remarks our contempo- people have known for some time—that secondary batteries are rary, "it will be readily understood that, inasmuch as lead oxide among the delusions of the age. When these appliances were first brought out, it was shown in the JOURNAL that their utility would be extremely limited, even if they did everything that could be suspected of such structures. When incandescent lighting divert the dynamo could not be shown to be on commercial way of working, it must be granted that interposing an extra pair of exchanges of energy in the process would only result in an increase of expenses, to say nothing of the additional labour and capital expenditure also thrown in with the disturbing battery. It was not known at this time that the structure of the so-called accumulator rendered it so uncertain in working that, for all practical purposes, no such arrangement could be said to exist. By statements appearing in a recent issue of the *Engineer*, however, we must cease to consider the Faure battery in any other light than that of a toy. How far this toy has proved to those who believed in it need not now be said.

It is no disgrace to any one to be unacquainted with the theory of the Plante battery, which is the foundation of all secondary batteries yet made; but a general knowledge of the structure and principle of these appliances is desirable for the clearing up of ideas and the explanation of the causes of difficulty and failure in working. According to the *Engineer*, it is not easy to learn how the Faure batteries are now made; but it appears that the cell is composed of two sheets of very thin lead, one 16 inches and the other 20 inches long, and both 6 inches wide. These plates are first thickly coated with red lead mixed into a thin paste with water, and a sheet of parchment paper is laid on this red lead. The sheets are afterwards covered with felt, and rolled up together; small slips of india-rubber being used to keep the surfaces apart. The roll is then put into a leaden vessel, and separate wires connected to the vessel and its contents. The cell thus constructed is filled with a weak solution of sulphuric acid, and the whole is ready for charging. "Such, then, is the Faure battery; nothing can apparently be more simple or easy to make." After this it is somewhat surprising to read that "the Faure battery has, in the strictest sense of the word, no commercial existence." Why does this conclusion follow upon such a seemingly favourable introduction? The answer is not far to seek.

One contemporary goes on to say that the battery just described —so simple that it can be made by any one used to laboratory work—can be charged either by a dynamo or by an ordinary gas main battery. So far, this is what has been said by all interested electricians. The accumulator would store up a weak or intermittent current during the day, and give it off as desired during the night in a form suitable for incandescent lighting—nothing simpler. Now comes the declaration that, after all is done by way of storing and charging the battery of one or more cells of the most approved fashion, "all these experiments have taught the same lesson—steady, that the battery is not trustworthy, save in the most experienced hands, and that even when used with great care it is liable to go to pieces and to prove worthless just when most wanted." The *Engineer* makes the serious suggestion that fire-engines are not half-a-dozen Faure batteries in existence which could be sent out to do a couple of nights' lighting with certainty. Strong language indeed is this to come from "the progress of electric storage" by the well-known circumstances of the previous failure of the Faure Company to supply charged batteries for the use of consumers. It is true that the managers have endeavoured to explain away this backward-ness on the part of the Faure Company is to confirm the impression which, in reasoning or reversing, gives up an uncertain premises. If by the existence of the battery, one or more cells are removed for the purpose of charging and discharging, the secondary battery cannot be said delivering during eight hours a current of 50. Each cell, in fact, represents over a hour-power of energy for one hour. Public demonstration will be made very shortly, and it is stated that probably within a few weeks, at the Crystal Palace Electrical Exhibition, 500 incandescent lamps will be shown running upon one set of 25 large cells of this new

as well while the battery is being charged as while it is being used; down, little can be more difficult to ensure than the permanence of the structure." We are sometimes oppressed with the sense of singularity when stating our deliberate conviction that, in matters of electric lighting, notwithstanding the dust and confusion raised by the multitudinous crowd of modern inventions, very little real progress is being made even from a purely philosophic point of view; while in the matter of business there is no progress at all. It is with considerable relief, therefore, that we record the opinion of the *Engineer*, that the red lead and suitable lead storage battery is at last here. It costs £40, and as cheap as it was in 1883.

It may be objected, against this very sweeping conclusion in favour of electrical accumulators in their present form, that the experiments at the Crystal Palace last spring, when the Admiralty Courts were lighted by Faure-Faure lamps served by Sellon-Volckmar batteries, and the occasional lighting of a railway train by the same means are proofs that there is some good in these inventions. A party of electricians have also enjoyed a few runs on the Thames in an electrically propelled boat; and Professor Ayrton has dazzled pedestrians, in the neighbourhood of Capel Court and elsewhere, with his tricycle driven and lighted by storage batteries. It may be answered that none of these trials can be considered to rest upon an ordinary commercial basis. As for the Palace experiment, it is known that tens of batteries were employed in this service; but, at what cost will never transpire. Some results of this class have been noteworthy as improvements to persevere in the same road; but it is absurd to pretend that commercially successful results have been even approximately realized. Those the dreams of many an enthusiastic journalist that the way is prepared for the universal distribution of power of electricity, in the same manner as milk is hawked from a cart—the same being warranted to wear and work well for lighting, cooking, heating, or driving domestic machinery—is yet far from realization. Again and again has this result been promised by the newspapers; but it is more certain than ever that many things must first happen. Forbearance among these necessary preliminaries we should be disposed to cite the emancipation of electrical science, whether concerned with problems of storage or otherwise, from the baneful influence of financiers or the Philippart stamp. With reference to the events which form the occasion for this article, *The Times* remarks that "sometimes the more new in terms of preparation; and the *Engineer*, with more knowledge, joins in the warning, and gives simple reasons for so doing: "There is not at this moment any secondary battery in existence, the success of which can be assured that the inventor would be justified in asking the public at large to invest in it." These are weighty words; but there is ample justification for their utterance at this time. What chance is there that the crude and uncertain Faure battery will continue to hold its own against everything that may be brought forward avowedly to supersede it during the next ten years? The world be a bold man who would affirm that science has said its last word on this subject; and yet, under any other conditions, the proposal of M. Philipart is worse than rash—it is foolish. It is in a measure fortunate, however, that the opportunity has been given to study the principles of the present condition of systems of electrical storage. The *Engineer* is to be thanked for the work it has done, and for the plain statements by which one more electrical illusion has been cleared away.

Iowa, March 1882

NEW ELECTRIC ACCUMULATORS.—It may interest those who have been looking forward to a practical application of electric lighting to private houses and to a possibly general use of the electric current from central offices, and of electricity, may be placed under ready command to know that great improvements have recently been made in electrical storage or accumulating batteries. It is stated that these improved batteries are of small size, have the facility and possess 24 times the storage capacity of those known as the Faure accumulators, and that they are of such a practical construction that they can be readily connected when necessary to the electric mains, and that the cost is less than that of the Faure. Each cell, of about 12 inches cubic foot in size, and consisting of sheet of lead, with metallic materials, is capable of containing 400 ampères, and of delivering during eight hours a current of 50. Each cell, in fact, represents over a hour-power of energy for one hour. Public demonstration will be made very shortly, and it is stated that probably within a few weeks, at the Crystal Palace Electrical Exhibition, 500 incandescent lamps will be shown running upon one set of 25 large cells of this new

THE COST OF ELECTRIC LIGHTING BY BATTERY.

IT has been announced of late that M. Trouvé has succeeded in producing a bichromate of potash battery capable of satisfactorily supplying incandescent electric lighting for domestic use. M. Hospitalier has experimented with these cells with a view to finding the cost of this method of lighting, and has communicated his results to the French Physical Society. With two batteries of six elements, connected in tension, six Swan lamps were maintained, when it regularly took from 8 to 5 ampères for 4½ hours, 5 minutes. The electro-motive force developed by the two batteries was 0·95 Siemens power per hour. The consumption of material was as follows:—Moulded zinc, 1·665 grammes; bichromate of potash, 2·300 grammes; sulphuric acid, 7·200 grammes. The cost of the material for these cells is easily found. The amalgamated and moulded zinc costs at least 1 franc per kilogramme; the bichromate of potash costs 2 francs per kilogramme; and the sulphuric acid 20 centimes per kilogramme. Thus in the present case the cost for a prime cost for material consumed of 7·70 fr., or (say) 6s. 2d., for maintaining during one hour six lamps of 16-candle power. If cost is increased to 9 fr., or 7s. 6d. for 16 candle-lamps. The cost of the same amount of light from common coal gas at 3s. per 1000 cubic feet would be 1·2d. This method of comparison is recommended the *Revue Industrielle* as a means of checking the fantastic calculations of amateurs of electricity. It is at least evident that incandescent lighting by battery power is not at this rate likely to be generally patronized.

Engineering, July 1887.

Engineering, June 1888.

The Faure Battery.

The first public exhibition of the Faure secondary battery in this country was that to which we have referred in another Note, where a number of Sturm coal oil lamps were maintained in incandescence at the conversazione at King's College on Saturday last. That we believe this quite a number of installations for lighting purposes have already been made in private houses, so that the full practical value of the apparatus will not long remain an unknown quantity. Meanwhile arrangements on a large scale are being made in London for the practical and commercial development of the invention. We have already taken pains to criticise the unwise and exaggerated claims made for the Faure battery in Paris with which the financial combination that had acquired the patents thought fit to take the public by storm, and pointed out that an interesting and valuable invention was likely to suffer from such a treatment. We are therefore the more gratified to learn that, in this country at all events, the value of the Faure battery is not likely to be damaged in the same manner, the sanguine of those gentlemen (especially that of Sir William Thomson) interested in the matter being a sufficient guarantee that no more will be claimed for the battery than it can fulfil. So far as light producing is concerned, Sir William Thomson probably suggested the real field for its usefulness, and as incandescent field it should be, when it be said that the battery would do for the electric light what a water-cistern does for an incessant house supply. It will also afford the means of obviating those interruptions in an electric light arising from irregularities in the motor, or from its temporary disablement, since if the dynamo-electric machine be employed to charge the batteries, and the latter are used to supply the light, the resulting current will be absolutely uniform. For working tramways not for some other purposes the batteries have been experimented upon with reasonable success, and doubtless much will be done with them in this direction. All this, however, is widely different from the original and sensational proposition to deliver batteries duly from house to house for giving light and power at prices competing with gas and steam; widely different, and infinitely more satisfactory, and within its legitimate limits, we may expect to see the Faure battery take a prominent place amongst the practically useful inventions of the day. Before dismissing the subject for the moment, we wish to correct two errors which have unfortunately appeared in a recent Note. The first referred to the date of the Faure patent, and stated that inasmuch as the date of this patent was the 26th of May, and that detailed descriptions of the arrangements had appeared in the public journals before that date, the validity of the patent may be called in question. So far from this being the case, the date of the patent specifying the Faure battery is dated January 11, 1881, long before any descriptions were made public, and subsequently patents have been granted in most other countries, including Germany and the United States, where objections of the most exacting kind successfully contested. The patent dated May 26, to which reference was made, is, we believe, for further modifications not yet ready public. The second error referred to the mode of charging the Faure battery. It was stated that it could only be charged by a voltaic battery. Were this the case the arrangements would of course be utterly without commercial value. As a matter of fact it can be charged by any direct current generator.

Accumulators and Metallogens.

Dr. H. Aron, of Berlin, who is well known for his investigations of secondary batteries, has entered scientific phraseology with the somewhat pacific term of metallogène, by which he denotes a mixture of any metallic oxide with collodion, the solution of gun-cotton in a mixture of alcohol and ether which is so largely used in photography. Dr. Aron's experiments commenced in the year 1883, when it appears that he, before the proposals of M. Faure became known, used plates consisting of spongy lead, which, however, he found in subsequent experiments suitable only as negative electrodes, the formation of anhydride of lead at the positive electrode probably disturbing the conductivity of the battery. Dr. Aron proceeds, it is stated, the use of minium, and once even asked his assistant to prepare a minium plate; he did not carry out the idea, as he considered it impossible to fasten the minium properly to its plate. Later on, however, he prepared a lead plate with a coat of minium and collodion made into a paste, and proceeding on those lines he obtained some interesting results. Metallogen seems to admit of further useful application. If the carbon of a Leclanché cell is brushed over with a paste of peroxide and collodion, the carbon rod needs no further adjustment, and may directly be placed with the zinc in the vessel containing the solution of chloride of ammonium without requiring a special porous cell. Dr. Aron further observed that to impart to the lead plate the necessary crystalline structure, it need not be placed in nitric acid previous to its further preparations, it will be sufficient to use a mixture of sulphuric acid with a little nitric acid in the battery, or, better still, to employ at first pure sulphuric acid, and then, after the lead has become covered with a thin coating of peroxide, to add the nitric acid, when this peroxide, being practically impenetrable to nitric acid, will prevent any too energetic action. Plates may thus be prepared to the depth of one half millimetre much more quickly than under ordinary circumstances, and they readily acquire a good charge, but they do not appear to be able to hold this charge so long as a Faure or Sellon-Volckmar battery.

would yield the illuminating power of 11·9 candles; but as an equivalent consumption of Paris gas only gives 9·6 candles, the ratio between them will be 81 per cent. The quality of the Paris gas will therefore be lower by nearly 20 per cent. than that of the London gas; in other words, the standard for gas in London being 16 candles, that for the Paris gas would be (16×20·8) 12·96 candles. Such would be the result if the matter could be treated by simple calculation. But this evidence of inferiority would not be correct: inasmuch as with the London standard burner the gas is consumed under much better conditions than with the Paris burner. The character of the burner has an unquestionable influence on the illuminating power of the gas; and not to take this fact into account is, of course, to make a very serious mistake—such a mistake as would be made by comparing two gases of different qualities on the one burner, for example, in a flooped burner, and the other in an ordinary straight-slit burner; although it is perfectly well known that, in order to obtain the light of 1 Carcel it is necessary to consume 2·7 cubic feet of Paris gas in the former, and 4·5 cubic feet in the latter. In this matter, therefore, the only conclusive experiments are those which are direct. The experiments made in the Municipal Laboratory of Paris by M. P. Leblanc, the Official Gas Examiner, and contained in a report of M. Huet, the Sub-Director of Works, gave 14·7 candles for a consumption of 5 cubic feet of Paris gas when it was burned in a London standard burner. The inference, therefore, would be only about 8 per cent.; and not 19 per cent. Even when operating with a Bunsen photometer, such as is used in London for official gas testing, it has, we are told, occasionally been found that Paris gas has shown an illuminating power of almost 16 candles. Proceedings then to endorse the discrepancies in the estimation of the value of the Carcel which have recently been brought out by M. Schlæsser's experiments (to which reference has already been made in the JOURNAL), M. Cornudet remarks that it is difficult, in the presence of such divergencies, to rely with certainty upon the average of a small number of tests; and therefore he says it will be necessary to avoid the results of repeated experiments, specially made in London with the Paris apparatus, and particularly with the same kind of photometer, in order to be absolutely correct. He considers, however, that in the meantime we shall not be very far from the truth in reckoning 14 English candles as the illuminating power of Paris gas, as compared with London gas of 16 candles. He then recites briefly the regulations in force in the Metropolis in regard to the pressure and purity of the gas, and the duties of the Chief Gas Examiner; and with these observations the first portion of the paper closes.

We next come to the statistics of the four Companies who were supplying London with gas at the time the paper was written. In preparing this section of his work, M. Cornudet has, of course, drawn extensively on Mr. Field's "Analysis," as well as on the half-yearly reports of the Companies, for the sake of brevity and clearness; and this he acknowledges. He has, however, converted the figures into their French equivalents; and this has necessarily involved labour for which the readers should thank him. These figures, though interesting and instructive to a foreigner, as showing the importance of the London Metropolis, are scarcely need reproduction in these columns. The tables give the quantity of coal and coke carbonized, the growth of the consumption in the years 1879-82; also the quantity of gas made and sold, the loss by leakage, and the annual percentages of increase in consumption. The stations of each Company are specified; and they are likewise indicated in a general map annexed to the paper, showing the districts of supply. M. Cornudet then proceeds to deal with some of the statistics in a manner which will be equally interesting on both sides of the Channel. He compares them with those of the gigantic Company in Paris (la Compagnie); and concludes the paper with some remarks on the conditions under which the gas companies carry on their business in country and suburban districts. These remarks are important enough to justify their consideration in another article.

Gas and Water Companies in the Money Market.

During last week the amount of business done in the Gas Market, with an absence of the violent fluctuations produced by sharp speculating on the dear coal question, left the Gaslight and Coke and South Metropolitan Amalgamation Schemes going their own sweet way. There is nothing but to wait and see how it will fare at the hands of the Board of Trade. In the meantime, the prices of the stocks are not high enough for recent buyers for a rise to realize upon; while they are too high for those who have to look to consumers upon now. The they remain pretty stationary. But they can scarcely be called firm: for even the buyers of the separate Companies's securities to admit that it is far from being free from serious difficulties, some of which have been already mentioned in our columns. In ultimate fate depends upon whether the Board of Trade may consider them to be susceptible of modification; or, on the contrary, may find them of such a nature as to place it beyond the statutory powers of the Board in regard to amalgamation to sanction. Them will probably be no lack of opposition, or demonstration of opposition, of a kind, on the part of the Vestries and District Councils; but if they can see their way to gaining anything by a compromise, they are not likely to take up the contention that the Scheme is absolutely objectionable, and *ultra vires* of the Board. Imperial Continental has been in good demand, and shows no advance of 6. Oriental, too, continues to improve.

* See Vol. XLI., pp. 938, 1007.

Three weeks ago we drew special attention to Water Stocks as giving good promise of improving prices. Since then all the Companies have made substantial advances; and their progress upward is still very well maintained. Chelsea and West Middlesex have gained 8 each; Southwark, 9; Kent, 6; and New River (which we noted last week as being underpriced) is now marked 5 higher.

The markets closed at the end of the week as follows:—

Incandescent Electric Lighting by Means of Accumulators.

MM. D. Mosnier and A. Gorrissen have reported to the French Metropolitan Electrical Syndicate upon the vessel operation of the application of the Sellon-Volckmar secondary accumulators to electrical lighting and mechanical traction. This is a part of the general inquiry undertaken by these investigators, at the instigation of a syndicate specially formed for the special purpose, and anxious to ascertain the truth of the matter, divested of interested colouring. The minutes of the report leave no doubt on the subject of accumulators is to collect, in the form of chemical action, electrical energy supplied to them from an exterior source, and to restore this energy in the form of electrical currents by virtue of inverse chemical reactions. This double transformation cannot be realized without a loss of work, which it is very important to value as exactly as possible. The duty of an accumulator is the ratio between the quantity of electricity supplied to it and that which is given up by it in its discharge. This coefficient was determined experimentally with a battery of 10 cells, of the 17·5-kilogramme *type*, which was received full charged. The battery was discharged, recharged, and then discharged alternatively four times. The final discharge was stopped at the moment when the battery was in the same electrical state as at the commencement of the first charge. It was thus ascertained that (1) the total quantity of electricity restored by discharging was equal to 81·95 per cent. of that supplied in the charge (this was the *duty in quantity* of the battery); (2) the sum total of energy restored by the discharge was equal to 62·14 per cent. of that supplied in the charge (this was the *duty in work*—which is really the most important result in practical use).

The capacity of an accumulator is measured by the total work which it is able of performing after having been entirely charged; but, in practice, accumulators are never completely discharged, because the last hours of a thorough discharge would only furnish a feeble flow of energy which it would be difficult to utilize. The energy remaining in the accumulator at this instant is not entirely lost, but constitutes a permanent reserve necessary for the regular working of the apparatus. (Would it be right to liken this quantity to the residual charge of gas in the dome of a gasholder?) The practical capacity of an accumulator, then, is less than its total capacity, and is measured by the useful work capable of being extracted from the cell before it has to be recharged. Thus it was found that the battery of 10 elements in question, containing 175 kilogrammes of useful material, was capable of supplying continuously a total work of 470,352 kilogrammètres, or 2·4841 horsepower-hours; which corresponds to 14·2 hour-horsepowers per tonne of useful material, or 70 kilogrammes of useful material per hour-horsepower. The mean yield of the battery was 14·76 ampères, or 0·84 ampères per kilogramme of useful material contained in one cell of the series. The capacity ascertained from the preceding determinations is not absolute; and it is probable that in consequence of improved methods of construction, the weight of

EXPERIMENTS ON THE ESTIMATION OF LEAD AS LEAD DIOXIDE BY MEANS OF THE ELECTRIC CURRENT.*

By Frank Dyson.

These experiments were undertaken to investigate anew the practicability of the determination of lead as lead dioxide in acid solution. The first experiments in this direction were made by Luckow† and by Moor.‡ They used a solution containing copper and 2½ per cent of free nitric acid (calculated as anhydrous HNO_3), and obtained in this solution satisfactory results, weighing the lead as lead monoxide, into which the dioxide was converted by ignition. Luckow§ says: "The complete precipitation of the lead occurs only in the presence of at least 10 per cent of free nitric acid, if only lead be present. If the solution contain copper also, less free acid is required. With less than 8 per cent free nitric acid, lead is liable to be thrown down on the negative pole with the copper as metal."

Hilpert‖ proceeds in the same way as Luckow, but warms the solution to 60 degrees in Bohgreen. The work of Pierail¶ and Meeczatzi in solutions containing tartrates, and of Classen and Von Reis** in oxalate solutions, relates to the precipitation of metallic lead, and has therefore little connection with the present subject.

The substance used for analysis in the present experiments was lead nitrate whose purity was proved by estimating the lead. This was done by igniting the lead nitrate and weighing the residual oxide, PbO.

Two determinations gave:

	I.	II.	Theory
Weight PbO, obtained	0·6600	0·6723	required.
Weight PbO, theory	0·6365	0·6543	
Per cent of Pb	67·5600	67·5647	67·54

A solution was made of this lead nitrate containing 1·6600 grams to the liter, and 25 cc. of this solution were taken each time for analysis. Of this solution, 25 cc. should yield 0·6366 gram dioxide.

In a neutral solution, the lead was deposited partly as metallic lead on the negative, and partly as lead dioxide on the positive electrode. Three portions of the solution were then taken, and to No. I. 14 per cent of free nitric acid (calculated as anhydrous HNO_3), to No. II. 5 per cent, and to No. III. 10 per cent, were added. After sixteen hours' action of the current, the lead dioxide thrown down was found to be:

	I.	II.	III.	Calculated.
	0·6358	0·6355	0·6360	0·6366

The coating on No. I. was not strongly adherent.

In the next trial, No. I. received 10 per cent, No. II. 18½ per cent, No. III. 10½ per cent of free nitric acid. The results were:

	I.	II.	III.	Calculated.
	0·6360	0·6724	0·6360	0·6366

In the next trial, 50 cc. solution of lead nitrate were taken and ten per cent of free acid added. The results were:

	I.	II.	III.	Calculated.
	0·6218	0·6181	0·6452	0·6533

In No. III., owing to irregularity of the current, the dioxide came down unequally and scaled off readily.

A solution of copper containing 0·2360 gram copper in 25 cc. was made up, and three portions, each containing 25 cc. of this solution and 25 cc. of the lead solution, were subjected to the action of the current after adding to No. I. 5 per cent, to No. II. 8 per cent, and to No. III. 10 per cent of free nitric acid. The results were:

	I.	II.	III.	Calculated.
	PbO_2.	Cu.	PbO_2.	Cu.	PbO_2.	Cu.	PbO_2.	Cu.
	0·6358	0·2360	0·6324	0·2364	0·6375	0·2360	0·6366	0·2360

The copper was in all cases slightly black.

In presence of iron with 14 per cent, 7 per cent, and 10 per cent of free acid, the results were:

	I.	II.	III.	Calculated.
PbO_2	0·6031	0·6255	0·6236	0·6366

The lead ore scaled off badly, thus accounting for the low result. The electrodes used had areas of 19·18, 19·19, and 40·40 square centimeters respectively.

To sum up, one may say this method is reliable where the amount of lead is not too large and where there is a sufficient amount of free nitric acid present. Where the lead does not exceed 0·05 gram, it may be thrown down as lead dioxide and weighed on ordinary electrodes. Where larger amounts are present, aliquot parts of the solution must be taken, or a platinum dish may be made the positive pole. The lead dioxide washed by decantation.

Since these experiments were made, this method has been largely used in this laboratory for the estimation of lead in galena and in slags and mattes. From 10 per cent to 20 per cent of free nitric acid should be present; if there is too much, the lead dioxide, as fast as it is thrown down, redissolves in the nitrous acid resulting from the decomposition of the strong nitric acid. In slags and mattes, therefore, the decomposition and possibilities of a Faure battery which had been sent to him from the laboratory of the inventor in France. His words aroused much attention, and the staff of the leading journal being on the alert, a cleverly constructed leading article in the next issue of the paper was devoted to the subject. The main point made by the professor was in the announcement that a million foot-pounds of energy, available for the production of power, light, or heat, was stored up in the 75 lbs. weight of metal composing the battery in question. Large numbers have a wonderful influence on the popular mind, and therefore it is not surprising that such a nominally great power, boxed up in a few sheets of lead, should have thereby the newspaper writer, and probably many others besides. It was not long, however, before another scientific man arose to state that Sir W. Thomson's figures meant so little that the wonderful box of M. Faure was equalled in value, as a source of work, by a piece of common coal weighing 14 ozs., which could be sent anywhere in a letter. Much of the dispute between the two professors and their respective followers, which caused upon this striking disclosure, is more fencing with the main issue. The facts appear to be that Sir W. Thomson had allowed himself to indulge in a little imaginative computation, strictly true, of course, from a theoretical point of view; and that Mr. Osborne Reynolds, in answering him in such a peculiar manner, also dealt in an imaginative manner with facts which, although real enough in their way, are scarcely capable of practical interpretation. In other ways, however, Mr. Reynolds shows a capability of sticking in hard every-day truths which it might have been hoped Sir W. Thomson would have also shown, instead of making a parade of strictly theoretical considerations without qualifying them as such. Mr. Reynolds maintains that even where the source of power to be converted into electricity and back again costs nothing for maintenance—such, for example, as the water power of Niagara, to which Dr. Siemens looks, as becoming a supply of energy for almost the whole of the United States—the bare cost of the conductor, and means of converting the current into work, must be more, even as a matter of carriage, than the transport of so much coal or wood will be needed to develop the same power at a given distance. He also considers that the effect of the use of electricity for conveying power, &c., will only tend to enhance the value of coal, rather than to supplant it. These fundamental considerations are, of course, unaffected by the discovery of the secondary or storage battery, for if electricity in current will not compare favorably in cost with coal as a carrier of power, so much less will the bottled article affect the value of anything in which coal is used. The discussion is interesting as a specimen of scientific fencing; but we are disposed to question its utility, whichever side may be considered to have the weight of evidence in its favour.

THE STORAGE OF ELECTRICITY.

Our contemporary *Engineering* devoted a considerable amount of space in its issue of the 21st inst. to observations on M. Faure's secondary battery, intended to store electricity for transit, or for keeping over any required period. It points out the true place of the Faure battery in an electrical distributing system to be very different from that of a reservoir or gasholder in the case of water or gas supply, to which it may unthinkingly be likened. In reality, the electric energy in this battery is stored up precisely as power is stored in a coiled spring or a reservoir of compressed air. The fact is, of course, very remarkable, and may be useful in its way; but it is not storage as implied in the sense of the reservoir of water or gasholder respectively—*i.e.*, an arrangement of a superfluous portion of the thing employed, so as to be instantly available to compensate for irregularities of consumption. It is, as pointed out by our contemporary, more analogous to the storage of water in a cistern for carriage from one place to another as a substitute for delivering it through pipes. M. Deprez, in a communication to *L'Electricien*, also demonstrates that the useful effect of the Faure battery cannot be so much as is claimed for it. This able critic maintains that not more than 82·5 per cent. of the power spent in charging it can ever be obtained again in actual work. Meanwhile, it is unfortunate that the merits of M. Faure's invention are likely to be obscured in a haze of speculation which has already set around it. Financiers have obtained a hold of it, and are promoting the wildest calculations respecting the amount of busine and profits to be derived from the use of stored electricity for lighting and supplying power to the residents of Paris. Our leading contemporary does good service by exposing the fallacy of these estimates, and points out that even if M. Reynier's laboratory experiments can be always and everywhere repeated, small power could be obtained by the use of a gas-engine, at less-than one cent of 8 Faure battery and of the electric motor necessary to transform it into power, is regard to lighting the disadvantage is still more apparent. To obtain, say, 1000-candle power for ten hours, not less than 1650 lbs. weight of batteries would be required, even if the whole energy of the battery could be utilised; but as the energy of the current falls very rapidly after about two-thirds of the cit has been exhausted, a large additional weight of batteries would h to be provided. Assuming that, from these considerations, one t of batteries would be required to give out the light of 1000 candl for ten hours, this weight of apparatus would have to be charg delivered, and the engine collected every day, and if the pr paid by the consumer for all this service exceeded 3d. per hour would be hopeless out of competition with the current system electric lighting. It will thus be seen how little chance of succ for the Compagnie Anonyme de la Force et la Lumière, which is form to work the Faure battery system, possesses.

Stored Electric Motor Power.—

A few days ago a practical illustration of the above was given in Paris. An ordinary three-horse tramcar made a tour of the principal streets of the city by means of Faure accumulators, placed under the seats, and connected with a Siemen's machine placed beneath the floor. The apparatus is, however, somewhat heavy, for it is described as weighing fifty hundredweight. The machine, which makes twelve hundred revolutions a minute, sets in motion, by means of a pulley, an axle, to which are connected the chains which give impulse to the wheels. These wheels revolve sixty times to twelve thousand revolutions of the machine. The speed of the electric tramcar is stated to be nine and a third miles an hour on level ground, and five and a half miles on an ascent, though how a distance of thirty English miles was traversed in three hours at the above speeds, stoppages included, is not clear. The experiment was considered to be a great success from all points. It was the longest distance ever traversed by means of electricity. The apparatus was under perfect control, and the estimated cost is one half that of horse power.

SIR W. THOMSON ON THE FAURE BATTERY.

The secondary battery of M. Faure has afforded Sir William Thomson and other scientific notables a good exercise in correspondence in the columns of *The Times* during the past week. The Glasgow professor commenced the episode by describing, in his accustomed striking manner, the powers and possibilities of a Faure battery which had been sent to him from the laboratory of the inventor in France. His words aroused much attention, and the staff of the leading journal being on the alert, a cleverly constructed leading article in the next issue of the paper was devoted to the subject. The main point made by the professor was in the announcement that a million foot-pounds of energy, available for the production of power, light, or heat, was stored up in the 75 lbs. weight of metal composing the battery in question. Large numbers have a wonderful influence on the popular mind, and therefore it is not surprising that such a nominally great power, boxed up in a few sheets of lead, should have thereby the newspaper writer, and probably many others besides. It was not long, however, before another scientific man arose to state that Sir W. Thomson's figures meant so little that the wonderful box of M. Faure was equalled in value, as a source of work, by a piece of common coal weighing 14 ozs., which could be sent anywhere in a letter. Much of the dispute between the two professors and their respective followers, which caused upon this striking disclosure, is more fencing with the main issue. The facts appear to be that Sir W. Thomson had allowed himself to indulge in a little imaginative computation, strictly true, of course, from a theoretical point of view; and that Mr. Osborne Reynolds, in answering him in such a peculiar manner, also dealt in an imaginative manner with facts which, although real enough in their way, are scarcely capable of practical interpretation. In other ways, however, Mr. Reynolds shows a capability of sticking in hard every-day truths which it might have been hoped Sir W. Thomson would have also shown, instead of making a parade of strictly theoretical considerations without qualifying them as such. Mr. Reynolds maintains that even where the source of power to be converted into electricity and back again costs nothing for maintenance—such, for example, as the water power of Niagara, to which Dr. Siemens looks, as becoming a supply of energy for almost the whole of the United States—the bare cost of the conductor, and means of converting the current into work, must be more, even as a matter of carriage, than the transport of so much coal or wood will be needed to develop the same power at a given distance. He also considers that the effect of the use of electricity for conveying power, &c., will only tend to enhance the value of coal, rather than to supplant it. These fundamental considerations are, of course, unaffected by the discovery of the secondary or storage battery, for if electricity in current will not compare favorably in cost with coal as a carrier of power, so much less will the bottled article affect the value of anything in which coal is used. The discussion is interesting as a specimen of scientific fencing; but we are disposed to question its utility, whichever side may be considered to have the weight of evidence in its favour.

Storage Batteries.—Prof. Henry Morton recently read a paper on the storage of electricity in the meeting of the New York Electrical Society, at the Stevens Institute of Technology, in Hoboken. Edison incandescent lamps lighted the room, a two horse-power Weston electric motor stood on the future-table, and the lamps and motor were furnished with electricity from the Sellon-Volckmar accumulators. Professor Morton briefly described the principles involved in the present methods of electrical storage. He then explained the structure of the Sellon-Volckmar battery, which consists of plates, each made of a fine lattice-work of metallic lead, filled in with a peculiar mass, which was in one case a lead oxide and in the other lead sponge. The experiments made by the lecturer showed that each cell of two amperes for nine hours, with an electromotive force of about two and one-tenths volts, a quantity of current sufficient to supply forty-four of the Edison incandescent lamps of 16 candle-power, with only 80 pounds when ready for work, so that for each light of 16 candles, burning one hour, 10 pounds of battery should be provided. It is customary to add solely as a reservoir to contain the current required. Experiments with the lights in the room were made to show that the battery in many cases would only be required to act as a regulator, simply taking up the temporary excess of the entire amount of electricity used, and providing for a temporary deficiency. By connecting the lights directly with a dynamo, its current was made to fluctuate so that the lights flashed up or failed according as the current was strong or weak. By connecting the dynamo with the battery, so that any excess of current could flow into it, or any deficiency be supplied by it, the lights burned perfectly steadily. Touching on the question of using the storage batteries as a means of driving street cars, Professor Morton said that his measurements showed that each battery of 80 pounds weight contained energy equal to about 1,000,000 foot-pounds, and would thus take a one-horse car full of passengers across town, or from one end of the city to the other.

Charging Accumulators.

Owing to the high resistance of electric incandescent lamps as compared with arc lamps, the ordinary dynamo cannot be used to feed them unless they are grouped in series, or unless a shunt of a minute, sets in motion, by means of a pulley, an axle, to which are connected the chains which give impulse to the wheels. These wheels revolve sixty times to twelve thousand revolutions of the machine. The speed of the electric tramcar is stated to be nine and a third miles an hour on level ground, and five and a half miles on an ascent, though how a distance of thirty English miles was traversed in three hours at the above speeds, stoppages included, is not clear. The experiment was considered to be a great success from all points. It was the longest distance ever traversed by means of electricity. The apparatus was under perfect control, and the estimated cost is one half that of horse power.

Charging Accumulators.

Owing to the high resistance of electric incandescent lamps as compared with arc lamps, the ordinary dynamo cannot be used to feed them unless they are grouped in series, or unless a shunt of a little sulphides are dissolved in nitric acid, and the solution evaporated. A perfect and complete separation of the lead and copper is obtained. The small amount of sulphuric acid formed by the oxidation of the sulphides in nitric acid does not affect the accuracy of the determination.

ANOTHER ELECTRICAL SPECULATION.

A partial revival of excitement in the world of investors who believe in the eventual use of electric force for every kind of work under the sun is announced by a contemporary, which hastens to warn off those who might otherwise be victims of the astute financiers who have addressed themselves to the task of raising money, ostensibly for the purpose of working M. Faure's patents for the storage of electricity. M. Philipart, of European celebrity in connection with banking operations—which, however, came to grief some time since—is said to be receiving much support in France for a Company formed for the purpose of supplying portable electricity for lighting, motive power, &c. A peculiarity of this enterprise lies in the proposal to devote some of the enormous profits anticipated to be made in the electric business to the relief of the ruined shareholders of the ecclesiastic promoter's defunct bank. It is, perhaps, hardly to be feared that M. Philipart, or any of his followers, will achieve such success in this country if the experiment should be tried; but it is well to remark, as we are likely to hear loud things said of M. Faure's battery for storing electricity, that there is no commercial advantage to be expected from its use over what may be derived from the continuous current. We know what the electrical and magnetic power companies are doing, and should those even succeed in widely extending their business, the profit to be gained by the use of storage batteries would, still have to be proved. It is known that gas can be supplied through pipes with perfect success, as electric energy can be transmitted through continuous conductors; but the Portable Gaslight Company found that they could not send out gas in carts and make a good return, and the same fate would certainly overwhelm an undertaking to distribute bottled magnetism while the regular article, in bulk, is not yet established in the market.

A New Application for the Faure Battery.

—Recently a horse-car was run in England by means of the Faure accumulator and a dynamo machine connected by cog-wheels and gearing to the axles. The distances traversed were about 24 miles. The dead-weight of the car was 3½ tons; the speed reached seven miles an hour, although the car was not of the most advantageous build for the purposes of the experiment. The experiment was successful, stopping and starting the car being effected with great promptitude.

The Planté Battery for Electric Light Purposes.—The most promising of the recent inventions in electric lighting, so far as its application is concerned, is the secondary battery, with the use of which portable electric lights may be obtained. A resumption of ambient Planté Tessen, is the result of some experiments as to the efficiency of the Planté battery, as applied to electric lighting. The object of these experiments was to ascertain the power contained in charging the battery, and the hours. It took 9,500,000 kilogrammetres to charge the battery with 6,000,000 kilogrammetres, and the work returned was 3,800,000 kilogrammetres, or 40 per cent of what had been stored in the battery.

The Lighting of Carriages by Electricity.—

Particulars of the practical application of electricity to the lighting of carriages are to hand. The late Lord Mayor's carriage, when proceeding to and from the banquet held at the Guildhall, on the 9th inst., was lighted electrically, the current being generated from Gaudi's patent primary battery, placed under the coachman's seat. This is the first time a carriage has been lighted by electricity in England. The installation was carried out on a similar principle to that recently used by Baron Rechenthal in Vienna. The second instance is given by the correspondent, at Rome, of the *Morning Post*, who writes: "The Milan omnibus and brougham companies have made experiments to light their vehicles by electricity. The experiment was most successful, and it is considered likely that the system will be applied."

STORAGE OF ELECTRICITY.

A NEW secondary battery, of greatly enlarged capacity, is now attracting attention in Paris. It is the invention of M. Faure, but is confessedly a development of the well-known secondary battery of M. Planté, which is formed of sheet lead immersed in acidulated water. The latter gathers copiously on the recurved charging and discharging is repeated, through increasing thickness of the layer of peroxide of lead that is slowly formed by the process. M. Faure has conceived the idea of exciting the peroxide, with layers of minium, or the red oxide of lead, and by this means the capacity is greatly increased. The peroxide so formed is stated to have forty times the power of accumulation of the Planté. A battery weighing 75 kilogrammes will receive 1,500 kilogrammetres, or 400 ampère-hours, during one hour. As to the nature of the chemical changes that are exerted upon the surface of the minium in presence of the positive electrode, and to reduce lead on the negative, the peroxide of the reduced lead is oxidized, and the precharging lead is reduced. The battery was lately exhibited by M. Hyppite in the Society for the encouragement of National Industry. There were 21 couples weighing seven kilogrammes each connected in a Siemens excitation of minium sites, there furnished a work of 1,000 kilogrammetres, with about a third of M. Hyppite's figures, but the conditions were unfavourable. Next, a band of platinum, one millimetre long, 12 millimetres broad, and 0·05 of a millimetre thick was made to glow; then two incandescent lamps were lighted. The superiority to the Planté battery was still demonstrated. Some experiments were made lately at Hospitalfield by M. Faure's battery as a means of distributing electricity to any house or working machinery, and the results that may be supplied, and flow from the drawbacks of a system of canalisation. The method is also regarded as very promising for domestic electric lighting. A carriage, it may be added, has been lighted in Paris by M. Philipart, for obtaining from and by electricity, by assimilation of the irregular action of the heart. A Hospitalfield has pointed out the expensiveness of charging the Faure battery with electricity from chemical action.

APRIL 17, 1880.] THE ENGINEERING AND MINING JOURNAL. 271

NOTES ON BATTERY AND COPPER PLATE AMALGAMATION.*

FROM THE MINING LABORATORY OF THE MASSACHUSETTS INSTITUTE OF TECHNOLOGY.

By Robert H. Richards, B. S. Professor of Mining.

Very little has been published recently on this subject in the mining journals or the proceedings of societies.

The attention of experts has been diverted perhaps partly by the demands for pan amalgamation in refractory ores. Yet free milling ores occur in many localities, and it may be interesting to have on record the views and methods of running a small battery, especially as details of results do not seem to be accessible to students and investigators.

Rhodel, in 1881, under battery amalgamation, discusses the subject by stating that "Amalgamation on copper-plated platforms, troughs and other copper fittings," is very imperfect, and usually abandoned.

J. Arthur Phillips states, in 1867, under placer mining: "A well-amalgamated copper plate is considered as effective for saving fine gold as an equal surface of pure mercury."

In Dr. R. W. Raymond's reports, I find in two volumes mention of amalgamation by copper plates.

In 1871, in an admirable article by N. S. Keith on the preparation of amalgamated copper plates, he states: "The discovery of the utility of sand-amalgamated copper plates in the treatment of auriferous rock in the mill was simplified and cheapened the metallurgy of gold that it is now profitable to mine and reduce many gold-bearing ores and rocks that formerly would not pay."

In Dr. Raymond's report in 1872, J. A. Church discusses the use of copper plates with reference to his theory of amalgamation. I am unable to find any allusion to the use of amalgamation in either Hiltinger's or Gustzach-mann's excellent works on *Allgemeine Hüttenkunde*.

Our experience at the Massachusetts Institute of Technology has been as follows:

In the winter of 1872, the little five-stamp battery was started in good earnest. Small lots of ore, successively from North Carolina, Georgia, Colorado, and New Hampshire, were run in the mill and over the plates. After each run, the plates were cleaned up, and the amalgam retorted, gold, therefore, was not as clean as we could have hoped, but the yield of gold fairly would not pay.

In the winter of 1873-4, the battery was remodelled, for causes which will be partially accounted for later on in this paper.

After the last of these runs, the plate was scraped a second time, and, to our dismay, some more gold was obtained; a third time, and more gold. We began to wake up to the fact that we had been crediting North Carolina ore with Georgia gold, and so on. This difficulty seemed so apparent, and seemed so inextricable, that we well-nigh despaired of ever using the mill in making careful quantitative tests. I shall speak of this difficulty, in the course of this paper, as the overcoming of "dead gold."

Until 1876, we did nothing more with the mill, owing to other cares. During that year, however, we added a new expedient, or overcoming the overlapping error. It was to purchase the thinnest copper that could be found in the market, about 1/64 inch thick, and to use a new set of plates with each run, dissolving the old ones in sulphuric acid at the end of the run. This method of overcoming the dead gold. We found, to be sure, but after much trouble: and in this way we entirely overcame the overlapping error. The method was laborious and tedious, but it was the only one we knew of. Sometimes which we scraped off, about 62.75 of gold which had soaked into the plate, while the plate was in use. When the plate by only about 1/4 inch thick, it then stamped 60·6 kilos per hour. These figures are, however, only approximate, and vary somewhat as they depend upon the skill of the feeder. Either over-feeding or under-feeding lessens the yield.

Four tests have recently been made, two of them by myself, on ores from New Hampshire, one from Virginia, and one from Nova Scotia, which were sent to us through the kindness of A. Sewer Torrence, Esq., of the Ancora Iron Company.

I. The New Hampshire lot. This was composed mostly of quartz, stained yellow with iron rust, having cavities from which the iron pyrites had been dissolved. It contained a small percentage of pyrites, but no gold that was visible as we examined it by the lens. This lot contained some fine mica-schist, which was probably from the wall-rock.

This lot of ore weighed 321·6 kilos or 1427·5 pounds. A sample of it yielded to fire assay $4.14 in gold to the ton of 2000 pounds, reckoning gold at $17 per ounce troy. The total value, therefore, of the gold in this lot was $5.20.

The yield of gold in the different parts of the process was as follows:

Battery amalgam	$4.021
24 plates	.775
24 plates	.193
24 plates	.055
24 plates	.044
24 plates	.00
Stamp traps	.122
Total yield	$5.040

Stamps were assayed for gold as follows:

	Per ton.
Ore sample	$4.14
Pulp sample as sand went to plates	1.227
Pulp sample as sand went to waste	1.227
Pulps collected from overflow	1.227
Coarse tailings	1.705
Fine tailings	.705
Residue in battery after 9 hours	2.58
The total value of the ore	5.20
The total value of the amalgam	4.021

or 85·2 per cent of the gold was saved. This, reduced to value per ton, is as follows:

	Per ton.
By fire assay	$4.14
By amalgamation	3.53

85·2 per cent saved by amalgamation.

The poverty of the lean pyritous concentrations found by us corroborates the conclusions arrived at by Professor Hitchcock, who states that he has universally found the gold in these mines to be in the pyritous ore, intimately associated with the pyrites, as it is in most other localities.

II. The second lot of ore was taken from the same locality as the first, but it was taken at a different place. The lot weighed 402·5 kilos (or 885 lbs.).

* A paper read before the American Institute of Mining Engineers, at the New York Meeting, February, 1880.

FAURE ELECTRIC ACCUMULATOR COMPANY (LIMITED).

An extraordinary general meeting of the shareholders of the above company was held at the Cannon Street Hotel on Monday last, Sir A. J. Otway in the chair, for the purpose of ratifying, or otherwise, the following agreements which had been provisionally entered into:—1st. An agreement between the Faure Electric Accumulator Company (Limited), of the one part, and the Electrical Power Storage Company (Limited), of the other part, for the sale by the Faure Company to the said Storage Company of the remaining interest of the Faure Company in the said Storage Section, and Yetchmar in England, on the terms and conditions mentioned in the said agreement. 2nd. An agreement between the Société la Force et la Lumière (Faure Zipernowsky and the French Electrical Power Storage Company (Limited), for the purchase by the Faure Company of the rights and interests of the Société la Force et la Lumière in the French Electrical Power Storage Company (Limited), on the terms contained in the said agreement. 3rd. An agreement between the Faure Electric Accumulator Company (Limited) and the French Electrical Power Storage Company (Limited), for the sale by the said Faure Company to the said French Company of the property in Paris belonging to the Faure Company, and providing for the Faure Company subscribing for shares in the said French company, as provided in the said agreement. The Chairman, in opening the proceedings, stated that the meeting was one of considerable importance. Certain contracts had been provisionally signed by the Board, but they would possess no validity until the shareholders had approved and ratified them. They had been chosen in pursuance of the policy which had already been indicated by M. Philippart and which had been unanimously approved by the shareholders on two previous occasions. After reference to the desire of the directors to be relieved from their office he stated that it was necessary, unless the matter was to fall through, that these agreements should be signed previously by the directors. He stated on the last occasion that he should not leave his place at the Board till he saw that that which he considered a set of honourable engagements taken by the directors towards the shareholders had been fulfilled, or unless the means were in sight whereby it could be fulfilled. He understood from their solicitor that those means were now supplied for the same with one fully paid-up share in exchange for the two now held with £7 paid thereon. He understood that M. Philippart would be prepared to take back the old paid, with all the certificates upon dividing among the new shares, and when they were exchanged for the shares now held, he should consider his engagements as the nominee of the present directors as administrators was terminated. M. Philippart would remain on the Board, and it would be necessary to elect another director, and those two gentlemen, forming a quorum, would be empowered to add to their number such other solicitors as they considered fit. Mr. Campbell, solicitor to the company, Mr. Campbell, the solicitor, then read a statement on behalf of M. Philippart, briefly explaining the effect of the three contracts referred to. After the execution of the contracts they expected to be able to pay a dividend of 5 per cent. on the £1 per year, and he assured them the date of issue on the £2 paid on the 40,000 ordinary shares: said M. Philippart had taken powers for allotting that during February next they would be able to declare a further dividend of at least £1 a share. As to the value of the inventions, he referred to what he stated on the 6th of November. The Storage Company could not, he said, nearly execute all the orders it received, although probably the loss of accumulators monthly, would be more than made up to the prime cost, the cost of maintenance, and the profit of the accumulator. The yield was now certified as to over 90 per cent. They had given up all idea of liquidating their company on account of legal difficulties, and must now, because they were the first in the field. Mr. Campbell having read Section 3 in effect of the first agreement, said that the Campbell having read Section 3 in effect of the first agreement, said that the second was between the Company of the patentees' interests of the Société la Force et la Lumière by the Faure Electrical Power Storage Company. Therefore, assisted by this agreement, the Faure Company would have possessed of 22 per cent. of the Faure, Sellon-Volckmar, and Volckmar process for French colonies. The third agreement was between the Faure Company and the French Electrical Power Storage Company, by the object being to sell to that company certain property in France which the Faure company now possessed, the Faure Company still the money arising from this sale, subscribing for certain shares in the French Electrical Power Storage Company.

The Chairman then called attention to the fact that the Faure accumulator originally manufactured from contract A2700, was said that the Faure a quantity of casts, which could only be taken out slowly because of the slowness of the discharge. What had been done was to make the cells hold much more for the same size, and give it out more quickly. The cells had much more coal tolerance had been made in the most direction. The accumulators which had been tested thirty were certainly twice as good as those originally sent to the experts last year. Hence the experimental tricycle could now run a measured mile in 40 minutes a rate that was impossible three days ago. The accumulator was also in 40 minutes a rate that was rejected. Two cells of giving out power was also very important to accumulators at sea. But in the matter of propulsion the giving out of energy quickly was also important.

The Chairman, in replying to a question, said he had no desire whatever to say anything unfriendly to the policy of M. Philippart in its general terms, but he was unable to agree with that gentleman in the procedure by which he proposed to carry out that policy. M. Philippart addressed the meeting in French, and intention to proceed with the matter was in his understanding. The Chairman, in a few words, explained the resolution, observed that if this meeting ratified them the ratification would be complete. The directors were not responsible for them. The resolutions were adopted unanimously. In reply to a question, he said the Faure director, who would possess satisfactory references. Mr. Campbell, on behalf of M. Philippart, stated that the shareholders would be called together in February to and Mr. Philippart terminated the proceedings.

Mr. Philippart, in acknowledging the vote of thanks, said that his best way of showing his appreciation of same would be for him to pay the foreshadowed dividends.

THE STORAGE OF ELECTRICITY.

THE storage of electricity is a subject which naturally attracts great attention at the present time, which may without much exaggeration be described as the era of electric inventions, and thanks to the letters of Sir W. Thomson, the public has been led to believe that a great and wonderful discovery has been made, which is to give us light, heat, and power from wind energy is could provided—he alluded to the question of supplying every householder who had sufficient for the same with one fully paid-up share in exchange for the two now held with £7 paid thereon. He understood that M. Philippart would be prepared to take back the old paid, with all the certificates upon dividing among the new shares, and when they were exchanged for the shares now held, he should consider his engagements as the nominee of the present directors as administrators was terminated. M. Philippart would remain on the Board, and it would be necessary to elect another director, and those two gentlemen, forming a quorum, would be empowered to add to their number such other solicitors as they considered fit. Mr. Campbell, solicitor to the company, Mr. Campbell, the solicitor, then read a statement on behalf of M. Philippart, briefly explaining the effect of the three contracts referred to. After the execution of the contracts they expected to be able to pay a dividend of 5 per cent. on the £1 per year, and he assured them the date of issue on the £2 paid on the 40,000 ordinary shares: said M. Philippart had taken powers for allotting that during February next they would be able to declare a further dividend of at least £1 a share. As to the value of the inventions, he referred to what he stated on the 6th of November. The Storage Company could not, he said, nearly execute all the orders it received, although probably the loss of accumulators monthly, would be more than made up to the prime cost, the cost of maintenance, and the profit of the accumulator. The yield was now certified as to over 90 per cent. They had given up all idea of liquidating their company on account of legal difficulties, and must now, because they were the first in the field. Mr. Campbell having read Section 3 in effect of the first agreement, said that the second was between the Company of the patentees' interests of the Société la Force et la Lumière by the Faure Electrical Power Storage Company. Therefore, assisted by this agreement, the Faure Company would have possessed of 22 per cent. of the Faure, Sellon-Volckmar, and Volckmar process for French colonies. The third agreement was between the Faure Company and the French Electrical Power Storage Company, by the object being to sell to that company certain property in France which the Faure company now possessed, the Faure Company still the money arising from this sale, subscribing for certain shares in the French Electrical Power Storage Company.

The Chairman then called attention to the fact that the Faure accumulator originally manufactured from contract A2700, was said that the Faure a quantity of casts, which could only be taken out slowly because of the slowness of the discharge. What had been done was to make the cells hold much more for the same size, and give it out more quickly. The cells had much more coal tolerance had been made in the most direction. The accumulators which had been tested thirty were certainly twice as good as those originally sent to the experts last year. Hence the experimental tricycle could now run a measured mile in 40 minutes a rate that was impossible three days ago. The accumulator was also in 40 minutes a rate that was rejected. Two cells of giving out power was also very important to accumulators at sea. But in the matter of propulsion the giving out of energy quickly was also important.

The Chairman, in replying to a question, said he had no desire whatever to say anything unfriendly to the policy of M. Philippart in its general terms, but he was unable to agree with that gentleman in the procedure by which he proposed to carry out that policy. M. Philippart addressed the meeting in French, and intention to proceed with the matter was in his understanding. The Chairman, in a few words, explained the resolution, observed that if this meeting ratified them the ratification would be complete. The directors were not responsible for them. The resolutions were adopted unanimously. In reply to a question, he said the Faure director, who would possess satisfactory references. Mr. Campbell, on behalf of M. Philippart, stated that the shareholders would be called together in February to and Mr. Philippart terminated the proceedings.

Mr. Philippart, in acknowledging the vote of thanks, said that his best way of showing his appreciation of same would be for him to pay the foreshadowed dividends.

which naturally attracts great attention at the present time, which may without much exaggeration be described as the era of electric inventions, and thanks to the letters of Sir W. Thomson, the public has been led to believe that a great and wonderful discovery has been made, which is to give us light, heat, and power from wind energy is could provided—he alluded to the question of supplying every householder who had sufficient for the same with one fully paid-up share in exchange for the two now held with £7 paid thereon. He understood that M. Philippart would be prepared to take back the old paid, with all the certificates upon dividing among the new shares, and when they were exchanged for the shares now held, he should consider his engagements as the nominee of the present directors as administrators was terminated. M. Philippart would remain on the Board, and it would be necessary to elect another director, and those two gentlemen, forming a quorum, would be empowered to add to their number such other solicitors as they considered fit. Mr. Campbell, solicitor to the company, Mr. Campbell, the solicitor, then read a statement on behalf of M. Philippart, briefly explaining the effect of the three contracts referred to. After the execution of the contracts they expected to be able to pay a dividend of 5 per cent. on the £1 per year, and he assured them the date of issue on the £2 paid on the 40,000 ordinary shares: said M. Philippart had taken powers for allotting that during February next they would be able to declare a further dividend of at least £1 a share. As to the value of the inventions, he referred to what he stated on the 6th of November. The Storage Company could not, he said, nearly execute all the orders it received, although probably the loss of accumulators monthly, would be more than made up to the prime cost, the cost of maintenance, and the profit of the accumulator. The yield was now certified as to over 90 per cent. They had given up all idea of liquidating their company on account of legal difficulties, and must now, because they were the first in the field. Mr. Campbell having read Section 3 in effect of the first agreement, said that the second was between the Company of the patentees' interests of the Société la Force et la Lumière by the Faure Electrical Power Storage Company. Therefore, assisted by this agreement, the Faure Company would have possessed of 22 per cent. of the Faure, Sellon-Volckmar, and Volckmar process for French colonies. The third agreement was between the Faure Company and the French Electrical Power Storage Company, by the object being to sell to that company certain property in France which the Faure company now possessed, the Faure Company still the money arising from this sale, subscribing for certain shares in the French Electrical Power Storage Company.

The Chairman then called attention to the fact that the Faure accumulator originally manufactured from contract A2700, was said that the Faure a quantity of casts, which could only be taken out slowly because of the slowness of the discharge. What had been done was to make the cells hold much more for the same size, and give it out more quickly. The cells had much more coal tolerance had been made in the most direction. The accumulators which had been tested thirty were certainly twice as good as those originally sent to the experts last year. Hence the experimental tricycle could now run a measured mile in 40 minutes a rate that was impossible three days ago. The accumulator was also in 40 minutes a rate that was rejected. Two cells of giving out power was also very important to accumulators at sea. But in the matter of propulsion the giving out of energy quickly was also important.

The Chairman, in replying to a question, said he had no desire whatever to say anything unfriendly to the policy of M. Philippart in its general terms, but he was unable to agree with that gentleman in the procedure by which he proposed to carry out that policy. M. Philippart addressed the meeting in French, and intention to proceed with the matter was in his understanding. The Chairman, in a few words, explained the resolution, observed that if this meeting ratified them the ratification would be complete. The directors were not responsible for them. The resolutions were adopted unanimously. In reply to a question, he said the Faure director, who would possess satisfactory references. Mr. Campbell, on behalf of M. Philippart, stated that the shareholders would be called together in February to and Mr. Philippart terminated the proceedings.

Mr. Philippart, in acknowledging the vote of thanks, said that his best way of showing his appreciation of same would be for him to pay the foreshadowed dividends.

ELECTRICAL REVIEW.

THE CHEMISTRY OF THE PLANTÉ AND FAURE ACCUMULATORS.

[From *Nature* of the 19th inst.]

PART IV.—*The Function of Sulphate of Lead.*

IN our previous communications on the chemistry of lead and peroxide batteries, we have frequently alluded on the formation of lead sulphate and its importance in the history of a cell.

In Part I.* we showed that the local action that takes place at first energetically between the metallic lead and the peroxide is gradually diminished by the formation of sulphate of lead.

In Part II.* we stated that in the original formation of a Faure cell, sulphate of lead is oxidized on the one plate, and reduced on the other. We also described an experiment in which two platinum plates were covered with lead-sulphate immersed in dilute sulphuric acid, and placed in the circuit of a galvanic current; the result being that "the white sulphate was decomposed to a large extent on each plate, the positive being covered with deep chocolate-coloured peroxide, the negative with gray spongy lead."

In Part III.* we showed that on the discharge of a cell, lead sulphate is the ultimate product on both plates.

It might naturally be inferred from our previous statements that in the re-charging of a cell, this lead sulphate would be oxidized on the one plate and reduced on the other, as in the original formation. This matter, however, has given rise to some controversy. All subsequent experimenters admit the *oxidation* of the lead-sulphate, but Dr. Oliver Lodge could not obtain any reduction of it when pure sulphate was employed. Sir William Thomson also, when experimenting with two platinum plates and layers of sulphate, obtained only a doubtful indication of reduced metal. The question as to whether the sulphate is reduced or not on re-charging a Faure cell is one of vital importance; for if the sulphate formed at each discharge accumulates on the positive plate it would clog up the space, and, what is perhaps worse, a fresh surface of the lead would have to be oxidized (or rather converted into sulphate) at each discharge. Thus the positive plate will be continually corroded, and its life will be limited.

We have already replied to Dr. Lodge in *Nature* (Vol. XXVI, p. 312), but we thought it desirable to repeat the experiment with the platinum plates, especially with a view to determine whether the reduction was effected slowly or with any rapidity. We fastened 20 grms. of the white sulphate upon a negative plate by binding it round tightly with parchment-paper, placed it vertically in the sulphuric

* See ELECTRICAL REVIEW, pp. 21 and 211, Vol. X., and p. 61 of Vol. XI.

acid, and passed a continuous current of somewhat under an ampère. The hydrogen was at no time wholly absorbed—indeed the greater part of it certainly escaped—but after a lapse of two days, small patches of gray metallic lead became distinctly visible through the wet parchment-paper; and these gradually spread in an irregular manner. At the end of ten days it was found that the whole of the sulphate, except a few small patches on the surface, was reduced to a gray spongy mass. Although there could be no reasonable doubt that this was metallic lead, a portion of it was tested chemically, and proved to be such.

It thus appears that the *reduction* of the pure sulphate of lead is an absolute fact, although it does not take place so easily as the oxidation.

In an actual cell the sulphate of lead is of course mixed with other bodies. Thus in the formation of a Faure battery, the minium is converted by the sulphuric acid more or less completely into peroxide of lead and sulphate. We have already described an experiment in which 4,189 cc. of hydrogen were absorbed on a plate, the materials of which were capable of absorbing only 4,021 cc., if the whole sulphate as well as the peroxide was reduced. In our notebook we have the particulars of four other experiments made in each case with the same or nearly the same, amounts of material, in which 4,199, 4,075, 4,216, and 4,387, respectively were absorbed, although perhaps in not one of these cases was the experiment continued until the action was absolutely complete. As, however, it may be objected that the amount of sulphate produced upon these plates was an unknown quantity, we have in a recent experiment treated the minium in the first instance with a considerable amount of sulphuric acid. This gave us a mixture which, on analysis, was found to contain 18·5 per cent. of sulphate of lead. This mixture, when submitted to the reducing action of a current yielded a mass of spongy lead that contained only a mere trace of sulphate.

As it seemed desirable fully to establish the fact that the sulphate of lead formed on the discharge of a cell is reduced in the subsequent charging, we took the quondam lead plate of a fully discharged cell, determined the proportion of sulphate to unaltered spongy lead, and submitted it to the reducing action of a current. The amount of sulphate on the plate before passing the current was found to be 51 per cent., but, after the passage of a current of about an ampere for 60 hours, not a trace of it remained.

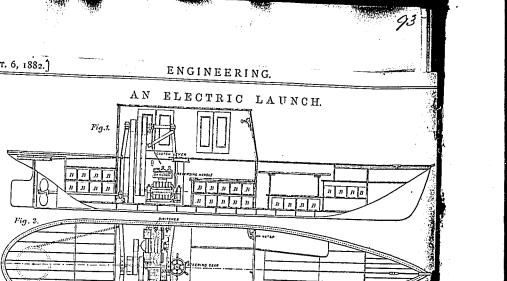
Hence it may be concluded that, during the alternate discharging and re-charging of a Planté or Faure cell, sulphate of lead is alternately formed and reduced on the lead plate, and that the plate itself is not seriously corroded. It would, however, appear desirable not to allow the whole of the spongy lead to be reduced to sulphate during the discharge, for two reasons, viz.: (1) because the supporting plate stands a chance of being itself acted on if there is not a sufficient excess of spongy metal; and (2) because the presence of this excess tends to facilitate the reduction of the sulphate.

We have already shown that sulphate of lead is produced by the local action that takes place between the peroxide and its supporting lead plate during repose. The same local action also takes during the charging of the plate, as was pointed out in our second communication, and this sulphate is, in its turn, attacked by the electrolytic oxygen. In this way the absorption of oxygen is forming the negative plate ought never to come to an end. In order to see whether this was the case, we allowed an experiment to continue for 115 hours, although the main action was over in about 40 hours. For the last two days of the experiment, the amount of oxygen absorbed was pretty constant, being about 9 cc. per hour; which is equivalent to 0·21 grms. of sulphate of lead formed and oxidized. The whole charge on the plate was 10 grms. of peroxide. This local action also takes place during the discharge, as is evidenced by the sulphate of lead formed on the negative plate always exceeding in amount that formed on the positive plate.

Through this local action taking place during the reduction of the cell, during repose, and during the discharge, the lead plate which supports the peroxide must be continually corroded more and more; and it is probably due to the insolubility of the sulphate formed that the destruction of this kind of secondary battery is so materially retarded in practice.

J. H. GLADSTONE.
ALFRED TRIBE.

AN ELECTRIC LAUNCH.

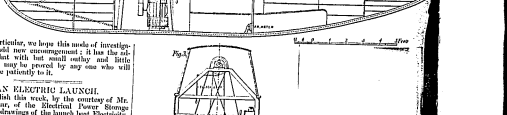


stood in particular, we hope this mode of investigation may obtain new encouragement; it has the advantages that with but small outlay and little training it may be proved by any one who will devote time patiently to it.

AN ELECTRIC LAUNCH.

We publish this week, by the courtesy of Mr. E. Volkmar, of the Electrical Power Storage Company, drawings of the launch boat Electricity, which made her trial trip upon the Thames on Thursday, September 28th.

The hull is of iron, 25 ft. long, 5 ft. beam, drawing 21 in. of water forward and 30 in. aft. She is a screw launch, the propeller being of the Colin Brown type, 20 in. in diameter, and with a 2 ft. pitch. The motor is calculated to make 350 revolutions per minute. Twelve persons can be accommodated on board, though only four were actually carried on the trial trip. The electric engines are nothing else than a pair of Siemens' dynamos, of the size known as D², and their motive power is furnished by Sellon-Volckmar accumulators, to which we shall shortly devote a detailed article. We may briefly remark that these accumulators are a modification of those of Planté and of Faure, but are made of specially compact design for the purposes of electric navigation. The cells each contain forty prepared plates, and weigh about 40 lb. They are about 10 in. square and 8 in. high, and are charged while the boat is lying at anchor by wires which come across the wharf from the factory, bringing currents generated by dynamos fixed in the works. There is room for a battery of fifty-four such cells to be stowed away, as will be seen upon the drawings, where the battery cells are marked B B. Only forty-five cells were used at the trial trip. They had a total electromotive force of 96 volts, and were capable of furnishing continuously for nine hours a current exceeding 30 ampères. When in action, the counter-electromotive force of the motors reducing the apparent strength of the current according to Jacobi's well-known theory of electro-magnetic engines. The accumulators have a total weight of somewhat less than a ton. The motors or electric engines are arranged so that either or both of them may be furnished with the current, there being a switch to each lead. There is also a commutator to switch into circuit any number of cells from forty upwards. The shafts of the motors can be thrown in or out of gear by means of an Ashpurst's friction clutch, which permits the pulley to be started and stopped with great facility without shocks. A reversing gear for the two motors is contrived by the very simple device of arranging two pairs of brushes for each collector or commutator, one pair having an angular lead forward, the other a lead backward. By a simple lever arrangement either pair of brushes can be pressed at will against the segments of the commutator. In practice this arrangement works well, the boat being very readily stopped by reversing the engines in this fashion. As will be seen from the

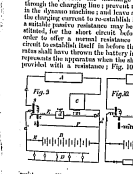


drawings, the motors are connected by belts to pulleys on a countershaft, from which a belt passes down to a pulley on the propeller axis, whose speed is thus reduced in the proportion of 850 to 350 revolutions per minute. The steering is managed by the same person who operates the switches, seated in the central cabin. A wheels being impossible in the absence of steam, this necessary feature is replaced by a large electric bell, also worked by the accumulators. The calculated average speed is nine miles per hour. This speed was actually attained on the trial trip from Millwall to London Bridge and back. The design and construction of the boat are chiefly due to Mr. A. Beckermann, C.E., mechanical engineer to the Electrical Power Storage Company.

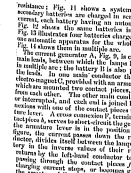
THE BRUSH SECONDARY BATTERY.

(Concluded from page 178.)

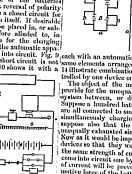
THE second part of the invention relates to devices to be used for automatically manipulating the current employed in charging secondary batteries. The objects sought to be attained by these devices are, firstly, that when no current is acting in the charging circuit the batteries in connection with that circuit will be short-circuited, so far as the charging circuit is concerned, and the latter will be short-circuited around each battery. Secondly, that when the charging circuit is established in the charging circuit, the short circuit around each battery will be opened and the battery thrown into circuit. Again, when the charging current stops each battery will be thrown out of circuit, and the line short-circuited as at first. These automatic operations prevent the discharge of the batteries through the charging line; prevent reversal of polarity in the dynamo machine; and leave a closed circuit for the charging current to re-establish itself. If desirable a suitable passive resistance may be placed in, or substituted, for the short circuit before alluded to, in order to offer a normal resistance for the charging circuit to establish itself in before the automatic apparatus shall have thrown the battery into circuit. Fig. 9 represents the apparatus when the short circuit is not provided with a resistance; Fig. 10 shows it with a resistance; Fig. 11 shows a system wherein three secondary batteries are charged in series by the same current, each battery having an automatic appliance; Fig. 12 shows the same batteries in multiple arc; Fig. 13 illustrates a battery charged in series with an automatic apparatus for the whole of them, and Fig. 14 shows them in multiple arc.



The current generator A, Fig. 9, is connected to the main leads, between which the lamps D are arranged in multiple arc; the battery B is also placed between the leads. In one main conductor there is fixed the electro-magnet C, provided with an armature-lever upon which are mounted two contact pieces, insulated from each other. The other main conductor is broken or interrupted, and is provided with a switch shown in figure, the current passes down the right-hand conductor, divides itself between the lamps and the battery in the inverse values of their resistances, and returns by the left-hand conductor to the machine, passing through the contact pieces f g. When the charging current stops, or becomes greatly reduced, the armature falls away from the magnet, and the circuit is broken between the contacts e and f, and completed through e and d. The left-hand conductor is thus interrupted, and the current then consists of the right-hand conductor, the coil connection F, the contacts d and e, and the left-hand conductor. When the charging current is again started the magnet C raises the lever E into the position shown in the figure, and the charging of the battery is resumed. Fig. 10 shows an arrangement identical with Fig. 9, except that a resistance H is inserted in place of the conductor F, and



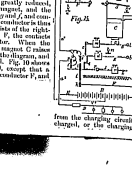
the lamps are differently connected up. In Fig. 11 there are three batteries B and three sets of lamps D,



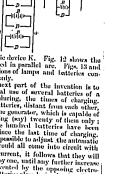
each with an automatic device K. Fig. 12 shows the same elements arranged in parallel arc. Figs. 13 and 14 illustrate combinations of lamps and batteries controlled by one device only.

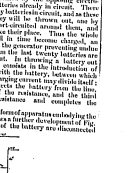
The object of this part of the invention is to provide for the unequal use of several batteries of a system between, or during, the times of charging. Suppose a lumbled battery, distributed from each other, are all connected to one generator, which is capable of simultaneously charging any) to only of them only; suppose also that the lumbled battery to have been unequally exhausted since the last times of charging. Now as it would be impossible to adjust the automatic devices so that they would all come into circuit with the same strength of current, it follows that they will come into circuit one by one, until any further increase of current will be prevented by the opposing electromotive force of the batteries already in circuit. There will now be only twenty batteries in circuit, and as these become exhausted they will be thrown, one by one, and the line short-circuited around them, and other batteries will take their places. Thus the whole hundred batteries will in time become charged, the automatic regulator at the generator preventing undue increase of current when the last twenty batteries are successively thrown out. In throwing a battery out of circuit the first step consists in the introduction of a resistance parallel with the battery, between which and the battery the charging current may divide itself; the second step disconnects the battery from the line, leaving it then thereof the resistance, and the third short-circuits the resistance and completes the operation.

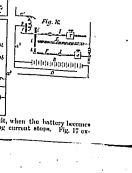
Fig. 15 illustrates one form of apparatus embodying the foregoing; Fig. 16 shows a further development of Fig. 15, wherein both ends of the battery are disconnected



from the charging circuit, when the battery becomes charged, or the charging current stops. Fig. 17 explains an addition to the devices illustrated in Fig. 16,







electromotive force of the battery B to reduced towards the close of the process of discharging. This will allow the magnet C to be energized if current is acting in the line a^1, and the lever E will be raised, and when it leaves S and L have the effect of throwing the battery into the charging circuit. If current is acting in a^1, the armature of the magnet C will be on the bottom stop, the short circuit through it will be open, the armature lever open, and the short circuit around the magnet C open, and consequently the latter is ready to act when the charging current again starts, and all this irrespective of any particular condition of the battery B. Again, the opening of the short circuit, while the charging circuit is not acting, prevents any unnecessary waste of current through the shunt.

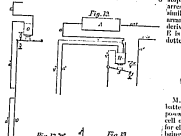
Let us now follow the operations which take place when the charging current starts, and the lever E, E, and I are at their lowest points. Matters have been so adjusted by means of the weights on the levers and the stop a, that the lever G will not respond to the attraction of the magnet C until the charging current, which excites the magnet, has reached a certain strength, approximately the normal one. Before this point is reached, however, the current may have been acting in the charging other batteries as already explained. When the proper strength is reached the lever G rises, and thereby disengages the arm attached to the lever E. By this time the lever G has approached nearer to its magnet C, whose attraction has then become sufficient to carry upward not only the lever G, but also the lever E, which is finally stopped by the contacts f g coming together. When the lever E begins to rise the contact e and of the lever I follows, owing to the counterweight at the other side of the fulcrum; thus the contact e is preserved, while the contacts i k are opened; this throws the resistance into the charging circuit. The battery B, continuing to move upwards, separates the contacts d e, and opens the resistance, thus throwing the battery charging current into the battery B. Finally, upward movement of the lever E is arrested by the catch, and the strong attraction of the magnet C for its armature is then carried in maintaining a good contact between the contacts f g, through which all the charging current now passes.

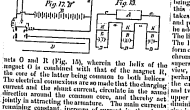
In Fig. 16 the lever lever, replacing the conductor F of Fig. 15, is provided at its extremity carries at the right hand end a contact piece d, which normally connected with the line a^1 another contact, which in conjunction with the first, connects the battery B with the line a^1. By means of this arrangement both ends of the battery are disconnected from the charging circuit when the lever E falls, because the contacts on F, as well as f and g, are then thereby separated. In Fig. 17 the circuit from the battery B to the electro-receptive devices B, is established when the contact lever is switched on to the contact pieces 5, 6, 7, 8. The contacts 6 and 8 are connected to a block 9, and are insulated from each other, but are forcibly connected with the ends of the battery B. The block is connected by wires 10 and 11 to the armature lever. When the current is active in the charging circuit, the armature is raised, as explained in regard to Fig. 15. This separates the contacts 5, 6 and 7, 8, thus disconnecting the electro-receptive devices from the battery and the charging circuit. When the charging current stops, the armature drops, and the devices are again connected to the battery. The object of the device shown in Fig. 17 is to insulate the electro-receptive devices from the charging circuit when the working current is acting therein, and is particularly applicable when a large number of batteries are charged in one line by means of a current of high electromotive force.

Fig. 18 illustrates a system of three batteries,

each with a controlling device K, charged from one source J.

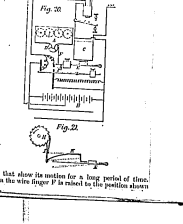
Fig. 19 shows a compound arrangement of the mag-





nets O and R (Fig. 15), wherein the helix of the magnet O is combined with that of the magnet R, the core 4c of the latter being common to both helices. The electrical connexions are so made that the charging current and the main current, circulate in the same direction around the common core, and thereby act jointly in attracting the armature. The main currents consisting constantly of the current in the almost closed circuit, due to resistance in the battery at the completion of the charge, will enable the magnet to raise its armature, and thereby all the charges already described in connexion with Fig. 18. When the charging current stops the armature will drop.

The last point sought to be attained by this invention is the record of the amount of electric energy imparted to a battery. To this end there is combined with each automatic current manipulator a time-measuring device, in such manner that while the charging current is acting to charge the battery the length of time it so acts will be recorded. When the battery becomes fully charged, or the charging current stops, the time mechanism stops also. As the electromotive force required to charge each cell is known, and the constant, it follows that the product of the number of cells by the ampère value of the charging current, and the time it is circulating, will form a reliable basis for calculating the money values of the stored energy. As, Fig. 20, is a clock movement, with



dials that show its motion for a long period of time. When the wire finger F is raised to the position shown by the passage of the current round the magnet C, the clock is free to go, but when the charging current stops, and the finger falls, the motion of the dials is arrested. The other pieces shown in the figure are similar to those of Fig. 15. Fig. 21 illustrates another arrangement in which the going barrel of the clock is derived from a spring K, which is bent when the lever E is raised, and allowed to expand again into the dotted position when the current fails.

M. Trouvé has recently modified the Sichromate battery to render it fitter for electric lighting purposes. This cell gives off no fumes, is a single fluid cell of high energy, and therefore especially valuable for electric lighting; but it has the great drawback of being inconstant in action. M. Trouvé has obviated this drawback by separating the liquid. He takes 150 grammes of a saturate of potash powder and puts it into litre of water, then, after shaking it, he adds drop by drop 450 grammes of chromic acid. The liquid warms up a little and the salt dissolves. The liquid thus prepared he lets cool, and does not force crystals in cooling. Mean while, it does not form chrome alum crystals when the cell is at work. The superscription of the existing liquid is 1·36 Twaite's view, the cause of the remarkable constancy which is perhaps explained by the absence of chrome crystalsom the carbons. Each element consists of two plates and two carbons supported by electro-platings at their upper part. This supporting consolidates the carbons and diminishes their resistance at the upper part. The zinc is arranged so as to be easily taken from the cell to be amalgamated. The batteries are arranged in sets of six elements placed in cases of oakwood. The carbons and zincs can be raised or lowered at will by a device like that employed in the Wollaston battery. In this way the power of the cell is regulated. With twelve elements ten incandescence lamps can be kept lit for five hours; but M. Trouvé has kept twenty lamps lit for two hours, each giving a light of ten and two. The electromotive force of the cell is 2 volts with good solution, and the intensity of current at the beginning on a short circuit is 110 ampères. The resistance is 0·07 ohms. Four batteries working a Gramme machine have produced 14 kilogrammètres of work during two hours without weakening in power.

Engineering, April 29.

Electric Storage Batteries.

One of the most interesting and novel exhibits at the Crystal Palace is the storage battery of Messrs. Sellon and Volckmar, by which the Alhambra counts are so beautifully lighted, through the medium of the Lane Fox lamps. We cannot fairly describe these batteries because the nature of the active material used in combination with the lead plates is at present kept secret: they consist of a series of lead plates perforated with 4 in. holes set very close together; within these holes is closely packed the material instead of being spread over the surface of the plates; by this means the necessity for protecting coverings of felt, asbestos, &c., is avoided, as there appears to be no tendency for the material to fall out of the holes; on the contrary it swells under the action of the current, and tends to tighten. Each cell consists of a number of such plates immersed in solidified water. About sixty hours are required to "form" these batteries, and a low tension machine is not necessary for the purpose, nor for subsequent charging, as those at the Palace are stored by the Brush or Schuckert generators. We are informed that these batteries are the outcome of combined patents of Messrs. Sewn, Sellon, and Volckmar, some of which are not yet published. According to the inventors, one of these cells having a capacity of .33 cubic foot and containing 62 lb. of "metallic composition," will yield when properly charged an aggregate current equivalent to one horse power of electrical energy per hour, giving off from 250 to 400 ampères at any required rate of composition are used; this latter size weighs 30 lb. A 5 horse power of energy for an hour, working up to 40 ampères per hour. Forty of these cells are employed to feed the 200 Lane Fox lights in the Alhambra Court. Of this installation we shall have much to say on a future occasion, for the present we confine ourselves to remarking that it has been admirably carried out by the Electric Storage Company, that the intensity of the light can be perfectly graduated by cutting out one or more of the cells from the circuit, and that with regard to these cells, experiment has shown their durability to be at least six months—experience with them does not extend to an earlier date.

The Sellon-Volckmar Accumulator.

To the Editor of Engineering.

Sir,—Certain statements have lately appeared relating to the above-named accumulators or storage batteries, the patents for which belong to the "Electrical Power Storage Company." With regard to these statements it is scarcely necessary to give any explanation to those who know me, but as many who may be in ignorance interested in the subject do not, I shall feel greatly obliged if you will publish the following particulars.

Having for long given attention to secondary batteries, and having succeeded in obtaining results which I considered of value, I took out in England in *September* last, certain patents, and subsequently later by others, those patents went at the same time have been applied for throughout the world, but for the present of awaiting the completion at my final specifications.

Towards the end of *December*, Mr. Volckmar, whose name is already known for the first time, was introduced to me as possessing secondary battery of much merit, which upon examination I found to contain essential points the same as my invention. The patents in question have been taken out by him in October in many Continental countries, but also in England, and then the position was, that although neither myself in his application for England, the Colonies and America, he had anticipated me for the Continent generally, and no arrangement was therefore made for the amalgamation of our interests.

At this juncture a patent was published, taken out by Mr. Swan, of November, in 1880, which was found to cover all my first specification, and to prevent me from obtaining title-deeds arising in the future. I purchased the rights for this patent from Swan, and from the publication of these patents was free to work.

I need only here detail the features of the Sellon-Volckmar accumulator, further than to say that in the judgment of some of the best scientific authorities in England it is an absolutely new and unique battery, which, if it does not lead us to any an infringement upon the Faure, which I assert is greatly superior in power and durability.

It was the intention of Mr. Volckmar and myself to deal with the question of patents, but a few individuals who were aware of the results obtained expressed the wish to join with us in their development, and to this course we were forced, *the interest arrangements of the Company are the concern of the public, any more than those of a proprietary*, inasmuch as no portion of the public was ever asked to subscribe, or did subscribe, one single farthing.

The Company was formed for the purpose of the patents to the Electrical Power Storage Company only concern those (all of high power) dealing with the Sellon-Volckmar cell first approved of and entered into with them.

The exact facts are that the *sole paid current and other expenditure already incurred*, the whole benefits of which were transferred to the company, and that we, the owners of the patents, who had the full right to sell, have, through the agency of our whole interest and profit in the business dependent upon the success of that, but a small amount of fully paid-up shares, which may, with the probable extension of capital, yield a return of 5 per cent. on the pounds now apply to three-millionths of one per patents *for the whole world*.

With regard to not guaranteeing the validity of the patents, the protective clause referred to is one which is always found in connexion with all agreements for the consent of standing over others the claims of purchasers to their patents, however sure they may be of their validity, and the usual clause, which I have always accepted myself in purchasing patents, was inserted in regular course. The case was, however, altered when applications to subsidize conventions or purchase of patent rights after an extent, and the clause referred to was at once introduced by the Power Company, and it was determined not to allow subscribers to subsidiary companies, against the contingency of no adverse issue by guaranteeing the return at all monies received.

The Electric Carbon Company of Scotland has nothing to do with the "Electrical Power Storage Company" which is the only one referred to in the newspapers. I did no even know of its formation.

With reference to Mr. Volckmar, who I have found to be a gentleman of honour and integrity, the matter has come before the Law Courts. Mr. Volckmar having immediately upon the original publication of the libel, commenced an action; and any discussion thereupon at present would be out of place.

May 25, 1882. John S. Sellon.

STORED-UP ELECTRICITY.

A FEW weeks since the scientific world in Paris was diligently interested by a paper read before the Société d'Encouragement de l'Industrie Nationale by M. Reynier, upon a new form of battery invented by M. Camille Faure, who, following in the steps of M. Gaston Planté, had succeeded—according to M. Reynier—in devising a battery in which three times as much electric energy can be stored up, as could be done by the Planté pile, the result being, that a large amount of force easily convertible into mechanical work, or adaptable for electric lighting, could be stored up in small and easily portable cells, could be transported from place to place, delivered from house to house, and that the great problem of a domestic electric lighting and power supply was thus solved. We have already in a "Note" (*vide* page 402 *ante*) indicated the arrangement of the extremely ingenious battery of M. Faure, but a more detailed description will find a suitable place here.

M. Faure's secondary battery is an application of a new discovery to the very beautiful and well-known secondary pile of M. Gaston Planté, which our readers will remember consists of two plates of sheet lead separated from one another and immersed in a glass jar of diluted sulphuric acid; if these two plates are connected for a time with the terminals of a source of electricity such as a dynamo-electric machine or a voltaic battery, oxidation and deoxidation take place on the two plates respectively, and after the exciting battery has been removed, the lead cell continues to give off a galvanic current of electricity so long as the deoxidation and oxidation of the lead plates continue by their returning to their normal condition. It was from the first observed that secondary piles of this construction produced better results after having been charged and discharged a great many times, a fact due no doubt partly to the increase of surface produced by the roughening of the lead plates under the decomposition, but chiefly to the formation of lead peroxide in increasing quantities, which was alternately deposited and decomposed as the cell was charged by the battery and discharged by the polarisation current.

M. Faure (whose name is well known in the scientific world as the inventor of the battery which bears his name, and in which the carbon element in a Bunsen's cell is made in the form of a bottle which contains the nitric acid) has recently introduced an important improvement in the Planté cell, by which its capacity is hugely increased, so that an approximate construction upon his principle is capable of producing a much greater current than that given off by a secondary battery of the old construction and of the same size. As the capacity of a secondary battery, other things being equal, is due to the amount of the layer of lead peroxide formed upon one of the lead plates, M. Faure conceived the idea of coating each of the plates with a thickness of lead sufficient to be converted by a slight oxidation into peroxide, and then completed the cell by placing between the two plates and holding on the coating of red lead. This couple is then immersed in acid contained in a cylindrical cell of lead and connected by its electrodes to the poles of a dynamo-electric machine or voltaic battery, and after having been charged and discharged two or three times, the red lead coatings of the plates are found to have undergone a change, the one having soon entirely transformed into peroxide of lead, while the other has been reduced to the metallic state, and as this result must store up forty times as much force as the plate and the deoxidation of that on the other, it would appear that what may be called the storage capacity of the apparatus depends upon the quantity of red lead carried by the plates.

There can be no doubt that in this way electricity may be "bottled up" and "stored" to an almost given by M. Reynier, that is to say, that a Faure unlimited extent, and in this bottled-up condition can be carried in reservoirs to a distance, there to be utilised until it is exhausted, just as a reservoir of compressed air, or a coiled up spring, may be carried for any number of miles, and can be made to give out power wherever required to a distant station. All this is true enough and obviously true, but the whole commercial success or failure of such a scheme must depend, as its commercial schemes must depend, upon its practical utility.

If electrical energy has to be conveyed from one place to another, it is a matter of small commercial importance in the abstract whether it is conveyed by means of metallic conductors or stored up in reservoirs and carried by road or rail; in this the commercial question involved being very much the same as that of the supplying of water by pipes or by water-carts. There can be no doubt, however, about which system is, save in exceptional cases, the most convenient, and unless it can be shown that the charging and transmission of storage reservoirs affords advantageous upon economical grounds, or very substantial conveniences of application over the system of transmission by conductors, we cannot see that its commercial application upon a large scale can be remunerative to its projectors, or that the promoters would wish to make the public believe.

That M. Reynier should have infused an undue amount of enthusiasm into his paper read before the Société d'Encouragement was almost inevitable, ing that he was describing for the first time results in advance of anything or of the same nature than had been achieved before, and it was perhaps probable that he should, for the greater glory of the Faure battery, have depreciated the capacity of that of Planté. But both in justice to the latter gentleman, and also to arrive at a just appreciation of the real value of the new discovery, careful investigation and comparison between the two batteries is necessitated. This has been partially done by M. E. Hospitallier since M. Reynier read his paper, and in the last number of our excellent contemporary *L'Electricien* the details contained are referred to, and the details of the experiments made are to be published in a succeeding number of the same periodical.

Criticising M. Reynier's paper, M. Hospitallier makes several statements made in that communication. M. Reynier maintained that the Faure battery would give out 80 per cent. of the power used in charging it, but as M. Hospitallier points out, under the best conditions not more than 70 per cent. of actual work can be transformed from mechanical into electrical energy by a dynamo-electric machine. M. Planté clearly demonstrated that his secondary battery could only give out 68 or 69 per cent. of the power charged into it, and as the difference between it and the Faure battery is one of degree and not of electrical power in the battery into mechanical power in the form of motion. Making allowances for all these losses it follows that the utmost useful work that can be got from the Faure battery is 52·5 per cent. of the energy employed in charging it, while in the Planté battery it is easy with the ordinary system of conductors to obtain 60 per cent. Passing over the question of the power which can be stored up in the Faure battery, M. Hospitallier makes an important statement in reply to the assertion of M. Reynier, that the Faure battery can only give out 80 or 82 per cent. of the power charged into it, and as the difference between it and the Faure battery is one of degree and not of principle, it is not probable that any greater power can be obtained; possibly it may be allowed for in converting the power into the battery into mechanical power in the form of motion. Making allowances for all these losses it follows that the utmost useful work that can be got from the

Engineering July 15, 1882.

ment of the lights, and accepting the statement that a battery weighing 165 lb. will develop one horse power for one hour, we have in the first place a dead weight of 1650 lb. of batteries. But this weight has to be largely increased, for the power developed by the batteries is not uniform from beginning to end, but is only practically so for about two-thirds of the time, after which it falls rapidly to nothing. As uniformity in power is of the first necessity for an electric light, it follows that only about two-thirds of the charge can be utilised, and, therefore, a large additional weight of batteries must be provided, to say nothing of provision for failures and accidents. It may therefore be fairly assumed that one ton of batteries would be the minimum required. To maintain a light of 1000 candles there one ton of charged batteries would have to be supplied and one ton of empty ones taken away. The mean distance over which this weight must be carried would be, according to the company's prospectus, 24 miles each way. The total charge on the ten lamps would be 25 6d., to include first cost, depreciation, carbons, charging a ton of batteries, carrying them five miles, and arranging them in the house where they are employed. Assuming that any one would submit to the intolerable nuisance of this diurnal landing and unloading, and even assuming that the light worked satisfactorily, how can so much be done for so little money?

While we have thus endeavoured to give a timely warning to the unwary and investing public in regard with the greatest fairness the exaggerated statements of speculators who would trade on the credulity of the uninitiated, we do not wish for a moment to undermine the value of M. Faure's invention, which is not only a valuable contribution to science, but under able and trustworthy commercial management, must have very important industrial applications. It would not be necessary to look as far from home as the other side of the Atlantic for instances of the applications of sound scientific inventions becoming paralysed by the action of speculating adventurers; and it would be hard indeed for scientific men if their reputation and success were necessarily bound up with that of the promoters of companies, of which the Compagnie Anonyme de la Force et la Lumière is probably the most ambitious over yet brought before the public.

Electric Lighting by Batteries.

A very important installation of the electric light fed from voltaic batteries has been made at the Compagnie d'Escompte, Paris. Owing to the number of valuable documents in the establishment the presence of a steam engine was considered dangerous; on account of fire; and loud and property rights were too exclusive to admit of recourse being had to a generating station in the neighbourhood. The engineer, M. Cornuyer, therefore fell back on the single-fluid bichromate of soda battery for the source of current. The liquid is in constant circulation through the cells and air is blown into them to maintain their power. The form of battery adopted was devised by M. Grenet in 1857 and recently improved by M. Jurriast. The cells are stored in the garret of the edifice. Each battery consists of 48 elements in two sets of 24 each. The solution is composed of 30 kilogrammes of bichromate of soda and 75 kilogrammes of sulphuric acid at 50 deg. combined with water to make up a cubic metre of liquid. The bichromate of soda is preferred to the bichromate of potash owing to the higher price of the latter. The negative plate consists of four plates of carbon plunged into a rectangular vessel and connected by a leaden top-piece or head. On this head are fixed two little ebonite tubes which plunge to the bottom of the trough and serve to blow into the liquid, thereby stirring it and assisting the depolarisation of the plates. The positive pole consists of six rods of zinc bound into a sheaf round a central electrode, and plunging into a chamber of caoutchouc containing mercury which amalgamates them. The zincs are so mounted that they can be raised or lowered at will, so as to put the battery in or out of action. The cells are joined up together by proper connexions. The liquid is distributed to the cells from a common reservoir by means of pipes, which fill a row of ebonite mounters by a stopcock at the will of the attendant. When these mounters are filled to a certain amount they tilt up automatically, and each empties itself by an ebonite funnel into the lower part of the cell below. At the same time the solution to a like amount overflows from the top of the cell and runs off as waste into another reservoir. This liquid can be restored to its old strength; but it can be used over and over again before this process is necessary. The air blown into the cells is supplied by the pneumatic apparatus already in the building. The compressed air serves both for the dispatch of messages and the insufflation of the elements. By these means a constant current is maintained in the battery sufficient for electric lighting. The electromotive force of each set of 48 cells is 82 volts, and the intensity of current on short circuit is 24 ampères. MM. Jurriast and Grenet estimate that each battery in good working order is equivalent to a horse power and a half of electric energy, or 112 kilogrammetres per second. The lamps employed are those of Siemens, Gravier, and Sozzi, according as they are best adapted for the department of the building. The cost of the installation is not yet known.

Engineering Oct. 13, 1882.

Electric Lighting.

Mr. A. Reckenzaun read a paper "On Electric Launches." In the first place he described the boat and described in our columns (October 6, 1882). Since that date the two motors with their counter-shafts had been replaced by one Siemens D dynamo connected directly to the screw shaft, upon which was a new propeller with two blades; its diameter was 17.7 in., pitch 21.4 in., and area of blade surface 60 square inches. The boat now only requires 43 ampères of current with 46 volts, the armature making 810 revolutions, and the speed attained being almost the same as before with 57.2 ampères. More recently Messrs. Yarrow and Company, in conjunction with the Electrical Power Storage Company, have fitted up another launch, which has been sent to the Vienna Exhibition. This is 40 ft. long by 6 ft. beam, and can carry forty passengers. The motor is a Siemens D* machine, which develops 7 horse-power with 80 volts, and a current of 70 ampères. The screw is two-bladed of thin forged steel, with a diameter of 21 in., and a pitch of 13 in. The weight of the motor and batteries combined is 2½ tons. During the trial the speed of the boat was over eight miles an hour, the current used at the time being 41.22 ampères, and the counter electromotive force 132.5 volts, with 62 cells in circuit. An account of the trip of the boat from the Temple to Greenwich will be found on page 66 of our present volume.

At the close of the paper another bearing the same title was read by Mr. J. Clark, of Glasgow. The launch he described is a wooden boat, clinker built, 21 ft. long over all by 4 ft. 4 in. beam, and drawing 12 in. of water with three or four persons on board. She is fitted with an electric motor coupled direct to the propeller shaft, and her power is derived from two battery boxes 3 ft. long by 8 in. wide, and 12 in. high, which can be utilised as seats. The batteries require recharging with chemicals about every four hours of continuous use, one battery driving the boat at three-quarters speed, while the other is being recharged. During several runs at Kilcreggan-on-Clyde, a speed of a little over five miles an hour was obtained, the motor running at 600 revolutions per minute. The weight of the boat complete, with batteries charged, is 4 cwt. Clark's electric launches are now being built by Messrs. Gilbert Boyle and Co., of Glasgow, of varying sizes, from 15 ft. long and four miles per hour speed to 30 ft. long and seven miles per hour speed. The author gave no clue as to the nature of his batteries or to the cost of working them. As it may be presumed that the power is generated by the oxidation of zinc, it cannot be doubted that the working expenses are heavy, although there are doubtless many cases in which this item will be more than counterbalanced by the convenience of being able to renew the action of the batteries by the introduction of fresh chemicals, instead of by the more tedious process of recharging by a current from a dynamo machine.

Sir William Siemens said that there were many applications in which the secondary battery would be found useful, but it was a mistake to suppose it could be employed for every purpose. For instance it was foolish to endeavour to adopt them for driving tricycles, but in launches, where the machinery was perforce very cramped, they promised excellent results. The great question was whether the secondary battery would last or whether it would perish. In order to test this point quietly he had put down batteries in his own house last autumn, and he had found them satisfactory so far. He charged them all day and at night he used both them and a small dynamo to feed his lamps. In the case of a launch the machine could not be taken with the boat and consequently the navigation would be confined to short stages. The cost of electricity and steam power under these circumstances would be about equal, but the former would give advantages in weight and space.

Sir James Douglas pointed out that an electric launch was much more easily swung from the davits of a ship than a steam launch, and that it offered greater security at sea. There was no fire to be put out if two or three waves were shipped, and the machinery would work under water. There was also a saving in the number of attendants, one man only being required.

Engineering June 1883.

Accumulators.

An interesting lecture room experiment, for illustrating the action of accumulators batteries has recently been made by Messrs. J. Elster and Hans Geitel, of Wolfenbuttel. It is poles of a dry battery of the Zamboni type are connected with the electrodes of a Holtz induction machine and the pile charged for about ten minutes, it will for several hours act as a miniature accumulator. Messrs. Elster and Geitel used an ordinary tin can, copper pile of 11,000 pairs, with plates of one centimetre square, suspended for convenience on a silk thread. The strength of this pile, which under ordinary circumstances would hardly have been perceptible, was increased so to give sparks of nine millimetres in length, and to work a small Geissler tube. This suggested the use of a dry Planté-Faure battery, which was made by placing lead foil discs between paper discs, of which one was saturated with oxide of lead and some silicate of potash was added to make the plate adhere. The battery worked well in a moist atmosphere and retained traces of its charge for fully twenty-four hours. Another, prepared with salicine and lead oxide paper discs, gave less favourable results.

ELECTRIC ACCUMULATORS.

WHEN, two years ago, M. Faure made public the modifications introduced by him in the secondary battery of Plantè, his hopes, and those of his friends, led him to believe that he was in possession of a new system of distributing electricity which would solve the whole problem of domestic and public lighting by this agency. It will be remembered how, a little before the Paris Exhibition of Electricity, M. Fontaine, then the active promoter of the Faure processes, proposed to the Municipal Council of the city of Paris, to light gratuitously the Avenue of the Champs-Elysées during the period of the Exhibition. This project was never carried into execution; indeed, under the conditions which were then contemplated, it was utterly impracticable, and as we pointed out at the time, it was very similar to a proposal for substituting horse-to-house delivery of water by hand, for the existing systems of main and service pipes. Practice has since that date done justice to such unreasonable expectations; it has been admitted long since that electric accumulators could not be so employed, and although they may be called upon to fill a more modest rôle, the part which is naturally assigned to them is of high importance. Except in some particular cases, it appears amply demonstrated to-day, that every electric installation of importance in which accumulators are employed, must also comprise the use of a motor, and an electric generator for charging them. The obvious advantage arising from the employment of accumulators in such an installation is this: Where the periods for illumination are only a small part of the day, say, five or six hours out of the twenty-four, it is possible to employ in charging the accumulators, a motor and generator of more moderate power than would be required for feeding the lights direct. Leaving on one side the question of price, it is not always convenient, or even possible, to locate machinery of relatively large dimensions in Pearson-top, legislation in the matter of steam power in crowded centres, is very minute and restrictive, and under such circumstances the use of accumulators is of the highest importance. If it is required to maintain a current of electricity over a period of five hours, corresponding to a consumption of energy of fifty horse power, we arrive at a maximum result with a motor of fifteen or twenty horse power, charging the accumulators during the rest of the day. It is possible that under such conditions the cost of the electricity produced may be somewhat times greater than that generated direct, on account of necessary expenditure—wages, coal and wear of accumulators, loss in duty of the latter, and so on. The reduced prime expenditure would thus be attended by an increased cost in working. But in many cases it may well happen that there is no choice between the two methods, and where the use of accumulators is imperative. Again, these apparatus may act as regulators to equalise the flow of the current to the lamps, and thus maintain the irregularities that so often arise from the slipping of a belt, or the accumulators may relieve steam-engines of the temporary stoppages of the motor. We need not carry these considerations further, remarking however that the use of accumulators is only possible where direct currents are utilised.

The real services that can be rendered by this class of apparatus are, it will be seen, considerable. Very naturally the reaction, succeeding the great expectations stimulating the first announcements, led many to deny the existence of any advantage, but since then the opinion of electricians has had time to become established. Careful inquiry has since demonstrated the advantages and the inconveniences of secondary batteries, their good qualities and their defects; if the experience derived from continuous and extensive practice has not yet been secured, at least careful investigations have been made to establish a definite basis for the determination of their efficiency and capability. In this relation we may refer the reader to the valuable experiments made by MM. Le Blanc, Jenbert, Pothier, and Tresca, and which will be found inserted in detail on page 83 of our thirty-third volume.

The greater number of accumulators now in use, are only modifications of the secondary battery of Plantè, to whom all the honour of the invention must be ascribed. The improvements made recently by M. Faure, the construction of whose accumulators is too well known to call for description here, consisted especially in increasing the storage capacity of battery by "forming" them direct with the application of a thick cost of minium on a sheet of lead. M. de Kabath, the inventor of an accumulator which is also now becoming widely known, has endeavoured, on the other hand, to follow as nearly as possible Plantè's method of forming his battery, but to obtain a far higher degree of storage power, by increasing the active capacity, but keeping the weight within moderate limits. The Kabath battteries which are made especially for use in connexion with the Maxim incandescent lamp, are manufactured at M. de Kabath's works, 17, Rue d'Argenteuil, Paris, where we have been enabled to investigate the mode of construction, formation, storing, and discharging. The details of the various processes are embodied in the following article, in preparing which we have also been assisted by a little pamphlet published recently by M. de Kabath as a sort of practical guide to the use of his accumulators.

The principal element of the Kabath battery is shown in Figs. 1 and 2. Let us imagine two series

Fig. 1.

Fig. 2.

of lead bands or ribbons, about 1 millimetre thick, 40 centimetres wide, and having 30 centimetres between the other 60 centimetres long. These latter are passed between two grooved cylinders, where they are rolled and corrugated in such a way that their length is reduced to that of the first series of flat bands (30 centimetres). A flat and a corrugated ribbon are then superposed alternately, and this is continued until a group of 160 or 190 bands has been put together, having a total width of 8.6 centimetres. This assemblage is then enclosed in an envelope of sheet lead, soldered together, as shown in the figure. There opening allow the liquid, in which the sections are immersed, to circulate freely. At the ends, the two faces of the envelopes are brought together and soldered. At one end a strip of lead slightly bent is added to serve as a rephore. Such is a single cell of the Kabath accumulator; finished it presents the appearance of a plate 38 centimetres long, 9 centimetres wide, and 1 centimetre thick; the weight being about 2.2 lb. The strips of lead are set close one against the other, as shown in Fig. 3, but in such a way that the corrugations of the grafted ribbons are not in the least flattened. On looking through the circular openings in the envelope, daylight can be seen between the flat and serrated strips.

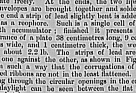

FIG. 3.

Up to the present time these cells have been coupled up in two types of portable and vertical accumulators. One of these, the laboratory type, Fig. 5, is formed of six cells placed in a glass chamber, the whole weighing 6 kilos. (13.2 lb.). The other, the so-called industrial type, is shown in Figs. 4 and 6, which indicate the reduction of elements and the box enclosing them. The type is made up of twelve cells and weighs 35 kilos. (64 lb.). In giving M. de Kabath has acted judiciously, considering that the accumulators are not likely to be moved constantly between a factory and the place of utilisation. In the greater number of cases, these

FIG. 4.

secondary batteries will have to be charged at the place where the current is utilised, and it is essential that they should be strong, durable, and easy of examination.

The two new types M. de Kabath has just put out with this object; are contained in rectangular wooden boxes, lined inside with hard rubber or ebonite, separated from the wood by a thin coat of asphalting mastic formed of arkanson and paraffin. The cells are placed edgeways, as shown in Figs. 6 and 9, parallel to each other; their flattened ends rest

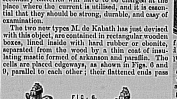

FIG. 6.

between vertical strips of ebonite, which act as guides.

This latter detail is advantageously replaced by glass plates, of the form shown in Fig. 7, having the same height as the box, and provided with two

FIG. 7. FIG. 8. FIG. 9.

grooves as indicated. These plates are placed at opposite ends of the box, and receive two cells forming a couple. Fig. 9 shows such a couple between the two glass guides, the box of course not being indicated. It will be noticed that the lead rephores are alternated, and are soldered to the envelope of the cells. With a metal of higher conductivity, copper for example, bathed in the surrounding liquid, a destructive hydro-electric action would be set up. The ends of the lead rephores are above the top of the trough, and they are united by screwed collars, seen in Fig. 6, and of which one is shown separately on the side of the box. This collar also receives the conducting rod. To avoid any direct pressure of the screw on the lead strips which would throw them out of shape, a small copper packing piece, shown as in Fig. 8, is introduced, on which the end of the compressing screw bears. The enclosing troughs are furnished with handles for convenience of transport. Two types of this new arrangement are in use, a small pattern corresponding to the vertical laboratory type described above, and a large size corresponding to the industrial model. A third and larger

BATTERIES AT THE PARIS ELECTRICAL EXHIBITION

The voltaic batteries on view at the Exhibition were almost all modifications of well-known types; but some of these modifications are worthy of being studied. To begin with the Daniell elements, as being the most universally employed and constant in its action, there was in the American Section a novel form which is employed on the Bunkhetead Railway at Turquie. It is the device of Herr Kohlfürst, and consists as shown in Fig. 1 of a glass jar A with a

FIG. 1.

construction *b b* at its lower part. This jar is covered with a cast-iron lid D to prevent evaporation, and a conical plate of pig-iron F, is connected to it by means of a brass pin *c* which is screwed into the lid, and carries at its upper end a terminal *e*. The zinc forms one pole of the battery, and the other is made of an S-shaped plate of lead lying on the bottom of the cell. A gutta-percha insulated wire *f* runs from this plate outside the cell through a hole in the cover, and serves for the other terminal. The bottom of the jar from the lead plate to the zinc barrow rack *h h* is filled with crystals of sulphate of copper, and over the rack is laid a perforated plate of unglazed earthenware *i*. The exciting liquid is a solution of sulphate of magnesia, which is poured into the cell through a funnel-shaped opening *j* in the cover. This is ordinarily kept closed by a cork.

The electromotive force of this element is about a volt, and its internal resistance about five Siemens units. It is stated to be very constant and requires little attendance; once set up it will last for six months however much it is worked, and a year if not in constant use. Meidinger and Krüger's batteries were formerly used on the Bunkhetead Railway, but by employing the battery we have described a saving of some 75 per cent. has been effected.

Another form of Daniell battery, with a reservoir for the sulphate of copper at the bottom is represented in Fig. 2, where the copper plate itself forms the separator between the saturated or copper solution below, and the sulphate of zinc solution above. It is the design of Messrs. Hunt and Little, and is constructed by the Western Electrical Manufacturing Company, of Chicago and New York. The agents of this company in England are Messrs. Latimer Clark, Muirhead, and Co., of Westminster. A very simple plan for keeping the two solutions from mixing in the Daniell cell was exhibited by Dr. Jamin Jenar, now of the Société Générale des Téléphones, Paris, but formerly of London. This plan is fitted with a jar, A, Fig. 3, a long glass (or cork, a cylindrical zinc rod B is inserted to serve for the positive plate, and a disc of copper D is placed on the bottom of the jar as the negative plate. An insulated wire runs from this plate through a hole in the cork as shown. The whole cell is filled with a solution of sulphate of zinc, and crystals of sulphate of copper are dropped upon the copper plate at the bottom, where they dissolve. The solution of

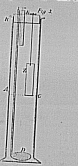

FIG. 3.

sulphate of copper thus formed is, however, prevented from rising into the upper half of the jar, where the zinc plate is fixed, by means of an additional piece of zinc, C, suspended in the liquid. Any sulphate of copper diffusing up as far as this plate is decomposed by the zinc, and metallic copper is deposited on the metal. There is thus a definite line of demarcation drawn between the two solutions at C, the level of the bottom of the suspended zinc. Dr. Jamar's cell answers very well as a standard, and the same device might be applied to the production of ordinary working batteries. When the circuit of a Daniell cell is open there is always a little wastage due to the reaction of the zinc upon the sulphate of copper. In order to suppress this M. Gaiffe has designed the form of cell illustrated in Fig. 4. This consists of a glass vessel B containing

FIG. 2.

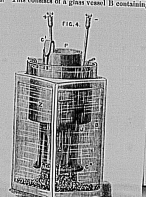

FIG. 4.

a zinc cylinder Z suspended by bent wires from the mouth of the jar; an inner chamber P, the upper part of which, J, is porous, and the lower part, S, is of ordinary glass; and a central cylinder of copper C, contained in the central vase. The copper cylinder is prolonged into a rod *c' c''*, which is bent back into the cell B outside of the porous vase and curved horizontally into a ring *c''*, which encloses the central vase. The cell is charged by a concentrated solution of sulphate of zinc or sulphate of magnesia, and crystals of sulphate of copper B are placed in the bottom of the central vase around the foot of the copper cylinder C. On dissolving, these crystals at first saturate the solution in the lower part S of the central vase, and when it rises to the line J, where the porous part of the vase commences, it permeates the pores and sinks by its density into the lower part of the outer vessel B.

THE ELIAS ELECTRO-MOTOR.

(For Description, see following Page.)

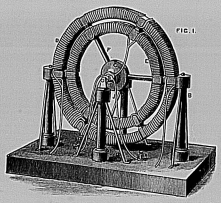

FIG. 1.

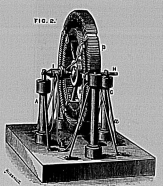

FIG. 2.

This permeation operates very slowly, and works cheaper, during which the circuit is opened, before any deposit of copper can be detected on the zinc. When the circuit is closed there is less internal resistance between Z and C; than between Z and C, hence the sulphate of copper which has sunk to the bottom of the outer vessel is first reduced, and the liquid in the exterior cell soon regains its original purity. The action then continues as in an ordinary Daniell cell. Further, the concentration of the porous pot by copper is avoided by preventing any contact between the pot and the copper plate.

A modified form of Leclanché battery, presenting some new features, was exhibited in the French gallerics by M. Mieche. As shown in Fig. 5, this

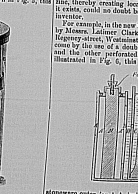

FIG. 5.

consists of a glass vessel A, containing at its upper part a cylindrical porous vase B, perforated with holes, which is attached to the electric cover of the cell. The vase is filled with fragments of plate of carbon; that is to say gas carbon, on which platinum has been deposited. From one of the terminals a platinum wire leads into the carbon and makes contact with the latter. The vase is traversed by an electric stem supporting a circular shelf or tray C, on which are laid two small cylinders of zinc, surrounded with mercury to amalgamate them. A platinum wire from the other terminal descends into the vessel and makes contact with the mercury. The external vessel is filled with water saturated with sal-ammoniac, or water thickened with a trace of its weight of sulphuric acid, or bisulphate of soda. The level of

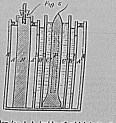

FIG. 6.

that water should not rise much above the level of the upper row of holes in the porous vase. The object of this is to make the greater portion of the carbon bound only by capillary action, whilst the zinc is entirely immersed in the liquid. The metal is therefore less easily dissolved.

M. Mieche claims for his cell that it will last a long time without recharging, and by its high electromotive force and low internal resistance is eminently adapted for working electric bells, or for telegraphic relays in series to, however, that small particles of platinised carbon can escape through the holes in the porous vase by the washing action of the liquid, and deposit on the mercury and zinc, thereby creating a local action. This defect, it is said, could no doubt be readily rectified by the inventor.

For example, in the new Howell battery, exhibited by Messrs. Latimer Clark, Muirhead, and Co., of Regency-street, Westminster, this drawback is overcome by the use of a double diaphragm, one porous and the other perforated, or rather slotted. As illustrated in Fig. 6, this element consists of a stoneware outer jar A A, inside of which is fixed a stoneware cell B B, called the "separator," having a number of narrow slots cut vertically in its wall, but not "through." A "separator" is placed on ordinary porous pot *c c* which contains a zinc rod F, kept sealing, by means of a thick layer of mercury in the bottom of the cell. In the space A' A' between the outer jar and the "separator" is placed a rod of carbon N, fitted in the usual way with a brass terminal for external connection, and surrounding this rod is packed a mixture of graphite and dioxide of manganese, in small pieces, together with some sulphate, or white manganese of commerce. The whole is sealed up with a compound of bitumen, and a small opening is left in the lid for the escape of gases.

The battery is charged with a solution of sulphuric acid in water (one part of acid to four parts of water), which is poured into the middle compartment B' B' formed by the "separator" and the porous cell. The latter is filled up with a solution of ammonic sulphate, made by dissolving 23 grammes of the crystallised salt in one litre of water.

The electromotive force of the combination is about 2·14 volts, or 1·2 per cent. higher than that of an ordinary Leclanché, and its internal resistance 4 from 5 to 6 ohms. This comparatively low internal resistance is attributable to the presence of white manganese, which has a higher conductivity than the black. The battery can be readily cleaned and, the eminent electrician, Mr. C. Hockin, M.A., has reported very favourably of its merits.

In the American Section there was a specimen of Helmuntz of potash cell, which gives good results. It was exhibited by Mr. A. Parti, of Philadelphia and Paris, and its chief peculiarity consists in the shape of the carbon plate. This is made in the form of a hollow cylinder or barrel, with vertical slots cut out of it from near the top to the bottom. It has, therefore, a vertical appearance, and encloses within it the zinc plate, which is also of a hollow cylindrical shape. The exciting liquid is a strong solution of bichromate of potash, and the electromotive force is said to be 1·65 volts, whilst the internal resistance is only 1·6 ohms. The result is a powerful current from a single cell, and hence the battery is well adapted for domestic purposes, such as ringing electric bells, or for actuating telephones.

While referring to the American Section we may also mention a more novel exhibit than in the "litharge battery," of Mr. J. Morgan Eldredge. The battery is of the ordinary form, and the plates are zinc and lead. The zinc cylinder is cast with lugs, by which it is hung from the mouth of the jar, and the lead plate is simply a square plate of lead placed on the bottom of the vessel. Powdered lithargo is strewed upon the lead plate and a solution of chloride of ammonia is filled in. In the chemical action of the cell, oxide of lead, chloride of ammonia, and dust are transformed into lead, water, chloride of zinc, and ammonia. No note of this battery are required, so we cannot speak of its merits, but the employment of lithargo as a battery material appears to be novel.

The element of Signor Piatti, in the Italian Section, is based on the observation made by its inventor that when powdered coke is pressed into a hard mass and inserted between the two plates of a voltaic element the carbon, though almost notably conductive within certain limits of pressure, does not "absorb strength," the cell, but on the contrary, and serves to render the exciting liquid more conductive and powerful. According to Signor Piatti, an element thus constructed lasts relatively longer without polarising than one in which the coke is absent. The cell he exhibited consists of the

Company of Inlays. 2. Experiments with Storing

The second annual meeting of the Faure Electric-Accumulator Company (Limited), was held at the City Terminus Hotel on Tuesday, June 28. M. Philippart presided and addressed the shareholders in French. He stated that his arrest in Belgium had been the result of spite in connexion with certain old questions pending with the Belgian Government. He was now out on bail, and he expected the matter would be decided in a fortnight, and that in a manner favourable to himself. If he were convicted he thought the position of affairs would be difficult, and he did not see how the business could go on in France without him. The enemies of the company — he meant those engaged in electricity, but in different systems, would endeavour to profit by these legal proceedings, but he had taken great precautions and used great efforts, and thus had been enabled to maintain the situation as it was. All the agreements which he was entering into, and was about to enter into, with the Government and others in France, were still remaining to be carried out by him as soon as the question connected with his arrest was finally settled in Belgium. He had been making experiments in Paris upon the propulsion of tramcars by stored electricity with great success. There were about 600 tramcars in Paris costing 60 francs per car per day for horse traction, and this figure, by the aid of their patents, could be reduced to 40 francs, which represented a saving of 500l. a day. What an advantage it would be to the shareholders if they could get the tramway company to enter into an agreement with them to give them a part of that amount! In reply to questions from the meeting, it was stated that the company had nothing further to do in England, the shareholders having approved of the sale to the remainder of the English patents to the Société Company, taking an interest in that company, whose patents were being worked in France, and to which they owed their profits. As to the 25,627 shares which M. Philippart had forfeited, on which 20s.10d. had been paid, they thus formed a set-off against the cost of the English patents and preliminary expenses; 19,600 of these shares had since been re-issued to the Société in Force et in Lumière. They had been issued as shares with 3l. each paid-up. The solicitor stated that M. Philippart was the only creditor and the largest shareholder of the Société in Force et in Lumière. The shares which had issued in St. Philippart's name had really belonged to the Société in Force et in Lumière, which now held at at least three-fourths of the shares of the Faure Company. This company had an interest equal to three-fourths in the French company, whose progress it was therefore very necessary that the shareholders should be informed about. After some discussion the meeting was adjourned to October 10. It is to be doubted whether the shareholders carried away either a clear or a hopeful view of their financial position. In England they have no active existence, and are looking for their profits to another company which they have practically sold to Ibis, a French company holds three-fourths of their shares, while they have an interest equal to two-fourths in the French company, and as if this were not sufficiently confusing, M. Philippart is the holder of shares and shareholder of the French company, and the shares which he has just forfeited to the English company have been returned to the French company, their paid-up value rising from 2l. to 5l. in the process. The shareholders are frankly told that their chances of a dividend depended largely upon the success of electric lighting in Paris, a very difficult problem, and that this was not to be achieved if M. Philippart be convicted. This is certainly the first time that a limited company has been addressed by a bailed-out chairman, and been told that he would carry their fortunes into court with him, and that if he did not reappear at the end of the trial they might consider them lost.

Storing Electricity.

If electricity is to become of general use to the community in the manner now prefigured by ardent electricians, and supplied to houses as gas or water is for a variety of domestic purposes, it will be a great advantage to have a convenient means of storing it up for a time. Secondary batteries are the likeliest apparatus for this purpose, and that of M. Gaston Plante, of Paris, has, up till now, been the best. This consists of two lead plates rolled together yet not touching each other, and plunged in water fortified with sulphuric acid. To increase the capacity of this arrangement M. Plante oxidises the lead by successive charges and discharges of electricity, until a coat of oxide and reduced lead forms on the surface of the metal. This is highly favourable to the production of the secondary current after the battery has been originally charged with the primary current. A single pair of plates of this kind having a surface of about ½ square foot (½ square metre) area, can store a quantity of electricity capable of rendering incandescent a platinum wire of 1 millimetre (·04 in.) in diameter for 8 continuous (about 3 in.) in length, for a period of ten minutes. Plante's battery is, however, too bulky for its power of storage to answer well in the general distribution of electricity which is demanded. Quite recently, however, M. Camille Faure has invented a modification of it which is far more hopeful. In this the plates are of lead and plunged in dilute sulphuric acid as before, but an almost boundless capacity is given to them by covering their surface with a layer of spongy lead, formed upon them by sending a current through them while immersed in the acidulated water. Red lead, or minium, is thus deposited on the positive plate and lead on the negative one, until the whole of the positive plate has been thus transformed. The plates are then enclosed in sheaths of felt kept in place by lead rivets, and the secondary battery is ready for storage. On being discharged again the reduced lead becomes oxidised, and the peroxide of lead on the other plate is reduced until the couple becomes inert. The great capacity of this contrivance for electricity is shown by the fact that one weighing 75 kilogrammes (165 lb.) will store a quantity of electric energy capable of performing a horse power of work for the space of an hour.

The Brush Secondary Battery.

After a long interval Mr. Brush has again appeared as a patentee in this country. His generator and lamp, although brought out in the early days of the revival of electric lighting, have held their own without change or improvement, while many compelling apparatus have been modified or have fallen out of notice. But however eminent the Brush system may be as a current chiefly for luminosity from mechanical development, and therefore it is desirable that it, like other systems, should make provision for the supply of electrical energy, should be supplemented by safeguards which will lessen the inconvenience, the dangers and annoyance of a stoppage of this light. For many months past we have heard that Mr. Brush was working at the problem of the storage of electricity, as a supplement to his method of generation and distribution; but it is only within the last few days that the details of his invention have been made available here. Up to the present time, we believe, his battery has not appeared in this country, and the only information that is available concerning them is to be found in his patent specification. This commences with a short description of the nature and formation of secondary batteries of the Plantè type, and is extremely interesting, from the fact that it appears to furnish a clue to the path along which Mr. Brush's mind travelled in working out his ideas. We shall endeavour to lay before our readers, in as concise a form as is consistent with a clear comprehension of the case, the explanation Mr. Brush gives of the internal processes that take place in a secondary battery, and shall then show how he applies these facts in carrying out his invention.

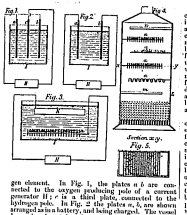
The most common form of secondary battery consists of two sheets of lead placed near together, but not in contact, and immersed in dilute sulphuric acid. When an electric current is passed through such an apparatus water is decomposed, hydrogen is evolved by, or combines with, one of the lead plates, while oxygen combines with the other and forms a coating thereon of peroxide of lead. This exhibits a lead cell being capable of combining with any acid, in practice that by the presence of the sulphuric acid employed. But if the exciting current be removed, it will be found that the apparatus has become a powerful battery, giving a current in a direction opposite to that of the exciting one. But this current is of short duration. If, however, the charging current be reversed from time to time, frequently during the first few days and more rarely afterwards, the capacity of the apparatus will be greatly increased. This constitutes the customary process of "forming" the plates of a secondary battery.

The formation of peroxide of lead on one of the plates progresses indefinitely so long as the exciting current is maintained, becoming constantly slower as the metallic surface becomes more and more protected against further action by the constantly increasing thickness of the coating of peroxide of lead thereon. This coating is a good conductor of electricity, and less oxygen is evolved at the surface of the peroxide coating. Now, if the exciting current be stopped local action, somewhat similar to that in galvanic batteries, sets in between the peroxide of lead and the backing of metallic lead that which it is in contact. By this action the peroxide of lead is reduced to a lower state of oxidation, while more of the metallic lead of the plate is oxidised by the oxygen thus made available. The fresh lead thus rendered doubtless acquires the same condition of oxidation as the original peroxide finally assumes. But the peroxide is never by this action reduced to the state of protoxide, as is proven by the colour of the coating, and the non-action on it of the sulphuric acid. When powerful enough to do so, a current will reverse the action it becomes useless for the development of a secondary current until freshly charged or oxidised. Thus is explained, as far as the oxygen plate is concerned, the cause of the gradual lowering of charge observed in lead secondary batteries. Further, since the conducting power of peroxide of lead hardly decreases as its oxygen is removed, the reason of the high electrical efficiency of the oxidised plates, after long standing uncharged, is also explained. When a plate that has lost its original conductivity is again recharged by an electric current for 24 hours, it will retain a higher charge than before, because all the lower state of oxidation is raised to the condition of peroxide, and thus some of the latter will be present than at the previous time of charging. This explains why the oxygen plates of secondary batteries constantly increase in capacity, even though the exciting current be applied at long intervals.

As the opposite plate of the battery hydrogen appears as the result of the charging current. This is produced at the surface being simply oxidised, or more probably forming a definite, but feeble, chemical combination with the lead. If such a combination exists it is probably a stable one so far as local action is concerned. But because the capacity of the hydrogen plate never becomes at all considerable when it is subjected to this action, it is useless. Hence in practice the oxygen plate soon acquires a far greater capacity, and the charge must be reversed before the hydrogen plate can act upon the hydrogen, and bring it into a spongy condition, in which it can retain a considerable quantity of hydrogen equivalent to the oxygen stored on the opposite plate. Thus it is the oxygen plate for the time being that receives all the frequent reversals of the charging action, the hydrogen plate remaining almost unaltered. This is the reason for the frequent reversals of the charge in forming batteries. When a previously excited secondary battery is discharged the peroxide of lead is thereby reduced to a state of lower oxidation, as already explained. Thus what was at first a good conducting envelope on the metal plate is now a non-reduced lead peroxide, and at the same time pure water is formed within the mass of lead oxide, and presents a perfect barrier to the passage of the current. These two causes account, so far as the oxygen plate is concerned, for the increase of resistance in secondary batteries during their discharge, and especially towards the end of the process, where it is also formed in the pores of the hydrogen plate.

The quantities of forming batteries by this process arise from the fact that the peroxide of lead formed on one of the plates is consecutively acted upon as formed on the metallic lead dish. The covering action does occur in all directions in forming, and to accommodate this the structure of the deposit must be more or less porous, or else the fine lead plates would expand. When the direction of charge is reversed the previously oxidised plate becomes alcoholic. Both the expansion and contraction may be rendered manifest by treating one side only of a plate, the other side being protected by varnish. When such a plate is oxidised the exposed side becomes concave, and when the oxide is subsequently reduced the same side becomes convex. During the processes of charging and reduction the expansion and shrinking does not occur in all parts of the mass at once, hence a thixotropizing action is set up, and the coating eventually peels off. Again, every time the plate is charged it forms a definite quantity of sulphate of lead, is formed within it, expands, and exercises a very deleterious influence, similar to that above, and aiding the disintegration by its separate volume.

The process of forming the plates of secondary batteries which constitutes the first part of the investigation avoids or eliminates the above evils almost entirely, and consists in charging the plates, which are ultimately to constitute the battery, in such a manner that a coating of peroxide of lead of sufficient thickness is formed on both of them. These plates are then associated together in the usual way, and an electric current passed through the apparatus in the manner customary in charging; one of the plates remains unchanged and constitutes the oxygen element, while the other has its charge reversed and becomes the hydro-



gen element. In Fig. 1, the plates *a b* are connected to the oxygen producing pole of a current generator H ; *r* is a third plate, connected to the hydrogen pole. In Fig. 2 the plates *a*, *b*, are shown arranged as in a battery, and being charged. The vessel I may be of metal and constitute the plate *r*, or the latter may consist of one or more previously charged plates which then become reversed, and are then ready to start further treatment to be paired with other charged plates, as usual, in the construction of the recovery cells. Several months of continuous or intermittent charging are required to produce a satisfactory coating of peroxide of lead; but the process of reversing the charge of one plate need not take more than a few hours.

This process of forming plates is applicable, not only to flat plates, but also to those upon which coherent porous lead has been deposited by electrolysis. When such plates are adopted they are first made electrically clean, and are then plated from a solution that will give a coherent deposit, such as oxide of lead in caustic alkali, and not from the sulphate, chloride, acetate, or nitrate, all of which give non-coherent deposits. Corrugated, ribbed, and perforated plates are well adapted to receive and retain the coherent coating, and have their corrugating uniformly filled with the deposit, but if treated in the ordinary manner by electro-plating the greater portion of the metal will be laid on the exposed portions and little in the cavities, in order to reverse this disposition the plate has the hollow portions filled with peroxide of lead, either dry or in a paste, and is then placed horizontally, prepared side upwards, in a solution of caustic soda or potash in a depositing trough as shown in Fig. 3, where *a* is the generator, l the bath, and K a plate to be treated. When the cavities on one side are filled the plate is reversed and coated on the other side, and again treated. Plates of other metals than lead, such as gold or platinum, may be used in the same manner as backings, and though two sources of electric current lose the oxygen by local action. When plates treated with deposited coherent lead are associated together in a secondary battery and charged, the reduced metal or coat of the plates is permitted much faster than ordinary rolled or cast metal, but not nearly so fast as the spongy or non-coherent lead, while the other plate absorbs hydrogen, but not nearly so fast as the former absorbs oxygen. It is therefore advisable to have recourse to the process of "forming" described above.

Another method of coating plates with porous lead is to make use of the metal in the oxide, and effect it by a reducing gas at a temperature insufficient to

cause fusion. Figs. 4 and 5 illustrate this part of the invention. The plates *a a*, whatever may be their form, are placed in a horizontal position in a chamber, and covered to a sufficient depth with lead oxide or nitrate, either in powder or paste. A stream of carbonic oxide, mixed with nitrogen, is then generated from the incandescent fuel on the hearth, and drawn upwards by the chimney, passing in its course downwards and forwards over the plates. The coating of lead oxide is then reduced to metallic lead, differing from those both of sponge lead and of the electrically deposited lead described above. It may be regarded as being intermediate in character between the two, but possessing many of the advantages of the latter, and being free from the disadvantages of the former.

Battery elements, previous to being "formed," may consist of a mass composed of metallic lead and non-oxidizable material which forms a support and active coating, united to a conductor *b*, and stiffened by a stay *c*.

(To be continued.)

Engineering, July 1882.

SECONDARY BATTERIES.

On Secondary Batteries, with special Reference to Local Action.

By Dr. J. H. GLADSTONE, F.R.S.

THE elements of which a (three) battery or cell is composed are modifications mainly see metallic lead, peroxide of lead, and dilute sulphuric acid. The reaction that takes place in the combination of the positive metal with SO_4, forming $PbSO_4$ (plumbic sulphate), and the reduction of the PbO_2 (peroxide of lead) by means of the hydrogen of the water, being also held to PbO (plumbic oxide), with the evolution of sulphuric acid, is also converted into sulphate of lead and water. The energy of the reaction which can be obtained from a cell depends upon the amount of peroxide of lead which is capable of being reduced. Now the arrangement of these secondary batteries is itself an arrangement of lead and lead peroxide, and if immersed in dilute sulphuric acid galvanic action at once sets up. "Local action" is, fortunately, soon diminished by the formation of sulphate of lead upon the surfaces of the lead plate and crystals of peroxide. When the two plates are brought into connection by means of a conductor external between them, but the local action on the positive plate is not stopped. This is shown by the much larger amount of sulphate of lead produced on the negative than on the positive plate. In experiments quoted by the author, the amount of sulphate of lead found on the negative plate was double the amount of peroxide of lead that may be thus destroyed on an average, and if not easily recognised, for the electrolytic force is not sufficient to set the current obtainable in the first instance in motion, local action, though, of course, the same amount of work cannot be got out of the battery. This local action takes place during the formation of a cell. One of the proofs of this is that a small more oxygen is absorbed than could possibly be taken up by the reduction of the minium used in a Faure cell; indeed, in one experiment which was continued for 115 hours, it was found that a large amount of oxygen was being continuously absorbed, though the main action was complete in less than forty hours. This was attributed to the formation of sulphate of lead at the extreme of the lead plate and its subsequent oxidation. This local action impairs the value of these secondary batteries, it hence impairs the value of these experiments which are important problem to ascertain what modification of the present arrangements will minimise if not entirely prevent it.

THE DANIELL CELL.

It is well known that the electromotive force of a Daniell cell falls after it has been in action for a time, and the fall is usually said to be due to "polarisation." The causes of the fall have been studied by Dr. C. R. Alder Wright, F.R.S., who recently read a paper to the Physical Society on the results of his investigations. The experiments on cell he employed contained two pairs of plates, one pair exposing double the area of the other, and the back of the latter being covered with gutta-percha, so that only the exposed surfaces came in action. The cell was of the gravity pattern, the two zinc plates being immersed in strong sulphate of zinc solution, and the two copper ones in a weak solution of sulphate of copper, which floated on the zinc solution. The zinc plates were both in the same horizontal plane, as were the copper plates, so that whether the large or the small plates were used the same compound column of fluid was between them, and hence the internal resistance R was the same. With this apparatus Dr. Wright first found the total fall for increasing current densities; and his results showed that there was no appreciable fall when the current density did not exceed 8 micro-ampères per square centimetre of plate surface (corresponding to a cell exposing 500 square centimetres of surface to a current of .004 ampère). With four to six times this density a diminution of the electromotive force of from 0.5 to 1 per cent. was brought about; and with currents exceeding in density 2000 micro-ampères per square centimetre (1.5 ampère with a cell of 500 square centimetres), the diminutions exceeded 10 per cent. It was further found that little differences was produced by using pure, commercial, or amalgamated zinc, or zinc coated with a film of copper respectively. Amalgamated copper plates gave more rapid rates of fall than electro-coated ones; and with dilute sulphuric acid surrounding the zinc the rate of fall was somewhat less rapid than with zinc sulphate solution. Dr. Wright also made a long series of observations to find out the maximum electromotive force when various qualities of solution were employed, in order to see how far the fall could be accounted for by the migration of the ions causing a stronger solution of zinc sulphate to accumulate round the zinc plate, and a weaker one of copper sulphate round the copper plate, than previously existed. This result shows that with nearly saturated zinc sulphate solution (specific gravity 1.4) and very dilute copper sulphate solution, the maximum fall in electromotive force is developed, it being less than .01 volts. Hence of the total fall in electromotive force produced when moderately strong currents pass, only a fraction can be accounted for by the effects of the migration of the ions. The general conclusion of Dr. Wright is that of the total fall in electromotive force of a Daniell cell on generating a moderately large current, usually referred to under the inappropriate name of "polarisation" only a small portion can be accounted for by the effect of migration of ions in causing differences of specific gravity between the fluids surrounding the plates. Of the remainder the majority is due to actions having their seat at the surfaces of the copper plate, and the rest to actions having their seat at the surface of the zinc plate. As a practical result it appears that the electromotive force of a Daniell cell with zinc and copper amalgamated plates, and either freshly deposited electro-copper, or amalgamated copper plates, is a tolerably readily reproduced standard, and it has this merit over the Clark standard element that a number of such cells will agree more closely among themselves than either forms of Daniell cell or than the Clark elements will do. The limits of variation among such Daniell elements being as ±0.2%, whereas among Clark's cells it is ±0.8, or thereabouts. On the other hand a standard Daniell falls in value in a few hours, or a day or two at most, whilst a Clark cell can be so constructed as to remain absolutely permanent in its indications (at a constant temperature) for months, and even one or more years. In the discussion which followed the reading of Dr. Wright's paper, Professor Clifton, of Oxford, the new President of the Society, stated that he had not found the Clark cell to justify his expectations; but that might be due to some fault in the particular cell which he had in his possession. This remark led Dr. Wright to explain that the electric laps supplied with the cell sometimes deteriorated under the influence of sunlight and became conductive. The cell ought, therefore, to be kept in the dark, or the electrode should be discarded. These cells could be set up by taking a piece of glass combustion tube (which was free from lead) and bending it into a U shape, one limb being very small, and the other thick. Pure mercury is placed in the bottom, and the mercurous paste poured in till the thicker limb is nearly filled, then a square of pure zinc is put on the top; the whole being sealed in melted paraffin. A platinum wire unmoistened by dipping it in sodium amalgam serves for the mercury electrode, and a copper wire covered to the zinc plate for the zinc electrode. Care has to be taken to expel air from the cell, and to keep the paste from shrinking.

Engineering, July 1882.

THE SKRIVANOW BATTERY.

This modification of Dr. Is Ilos's chloride of silver cell consists of a positive pole of zinc in an alkaline solution of 70 parts of caustic soda to 100 of water, and a negative pole of chloride of silver fused into a mass and enveloped in parchment paper. As made up for the pocket the zinc is in the form of a flat U-shaped plate of zinc, which contains in its hollow the chloride of silver packed round a silver plate. The whole is placed in a small wooden case with a close fit having a hole, ordinarily shut up, to allow of fresh liquid being put in when the cell is used. The connections are made all of silver. The weight of the cell thus accoutred is 90 grammes. The electromotive force is from 1.50 to 1.56 volts, a little higher than the ordinary chloride of silver cell. It is to be remembered that this result, like that of every battery extant, is probably 1.3 per cent too high, owing to the calculation used being on a much greater than the true ohm by Lord Rayleigh's measurements. The cell can give out a current of one ampère for one hour, when the liquid must be renewed. After two or three renewals the chloride of silver must be replaced. It of course is therefore an expensive battery; but its portability and cleanliness render it useful in theatrical effects for producing starlights on the heads of dancers. In the opera of La Farandole the dancers have circlets round the head with starlights mounted on them. Wires pass from the circlet to a belt or ornamental cestus round the waist of the dancers. Two Skrivanow cells on each side of the belt chair, form the electric generator. On the belt beside the battery a little commutator permits the corypher to control the light at pleasure.

USE A NEW ELECTRICAL STORAGE BATTERY.

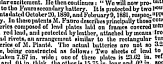
In a paper communicated to the Royal Society by Mr. Henry Sutton, of Ballarat, Victoria, and read before this Society by its President, Mr. Sutton urges that no system of supplying electric force can be considered as perfect until some means is used to so store the force generated that it may be drawn off equally and regularly, and that reservoirs ought to be between the generating machinery and the apparatus of whatever kind, to prevent the apparatus from being influenced by accidental little further, would perhaps not as such accidents in the machinery. Mr. Sutton himself has done a good deal to bring us nearer this aim. In the long series of his investigations, which comprise many different forms of cells, he first largely used lead as the negative electrode can only proceed with a sponge, as a special feature of which he claims that the injurious effect of the hydrogen, generated at the negative electrodes during charging was avoided. A sheet of lead in a porous pot, filled with dilute hydric sulphate formed the positive electrode; the negative electrode, also a sheet of lead, was placed in a solution of acetate of lead. The positive electrode of this cell is peroxidised during the charge, whilst at the negative the hydrogen replaces the lead in the solution, so that metallic lead is deposited on the sheet, and acetic acid, result as products. During the discharge the peroxide is reduced, and the just deposited lead oxidised and dissolved in the acetic acid; thus the original materials are reformed. Amalgamating the positive electrode had a very marked success. The lead is then more uniformly and rapidly peroxidised, and Mr. Sutton found this advantageous with the various modifications of this cell that he experimented upon. He constructed, among others, cells with porous amalgamated cylinders of either red or peroxide of lead as electrodes, also cells with parallel plates and red or peroxide between them. In this latter combination, the red oxide proved useless; perhaps because, as Mr. Sutton remarks in another part of his paper, red oxide of lead is a bad, whilst peroxide is a good conductor of electricity. The cells for which Mr. Sutton finally decided are not different in principle from the one that we described. As positive electrode he retained amalgamated lead; as negative he used zinc, iron, or copper, placed in a solution of their respective sulphates. During the charge the metal of this solution would be deposited, the resulting solution, sulphuric acid, being such that should, on the oxidation of the deposited metal, combine with the oxide and again form the original solution. The results with these cells were not only more powerful but also very constant. Really practical and economical, however, of these is only the copper cell. Zinc was discarded, as the plate would have to be kept amalgamated to prevent local action; and iron was set aside as it oxidised when not in use. The copper cell is free from such faults, and the charge of colour that here takes place during the charge makes it an exceedingly easy to tell when the cell is charged, that Mr. Sutton speaks of this change of colour as a veritable charging gauge. We know that the charge is effected by the blue sulphate of copper being decomposed into metallic copper and colourless sulphuric acid and water; the charge will therefore be completed when the liquid has become colourless, and again the discharge will approach to the end when the deep blue reappears. Mr. Sutton used the two metal sheets rolled up in a spiral, the copper sheet being a little shorter, and both perforated to allow a free circulation of the liquid; rubber loads, cut every ½in, kept the two plates separate from one another. With such a cell, 4 in. deep and 4 in. in diameter, Mr. Sutton obtained over two hours' effective work, in leading to red lead 1 in. of No. 28 iron. As a practical form of this cell Mr. Sutton proposes to fix a series of amalgamated leads in a box in grooves, as in Cruikshank's trough battery, and to fill the intervals between the plates with copper sulphate. He has himself two boxes on this plan, each containing 25 plates, equivalent to 50 cells; they can be charged from 30 Bunsens. It is not advisable, according to Mr. Sutton, to suspend crystals of the blue sulphate in the solution, as they would prevent the oxidation of the lead, it being essential that the solution becomes slightly acid before the peroxide will form. The addition of one or at best be local. It has, indeed, been difficult to discuss this matter sooner, for it was impossible to form any conception of the Faure battery before the public. It has been sold and repeated officially that in a Faure battery a considerable loss of time occurs before the current is sufficiently able to overcome its own back pressure, for one hour, or 3.25 foot-pounds per second per pound of battery. We have only seen an approximate answer to this question, on the Société d'Encouragement. Then it was for four pounds of the small; the battery weighed 220 lb., but instead of giving 1070 foot-pounds per second, it gave 1,200. Now, as the Faure accumulator makes have been working under most favourable conditions; it might have been delay for less than its maximum. We do not wish to draw any deductions from this experiment, which was, however, a very unfortunate one, and we will for the moment accept the 3.25 foot-pounds per pound of battery. We might here to remark that Mr. Tyler has calculated, by an extremely simple method, that a battery weighing 220 lbs. can, according to algebraical calculation which is published in the Transactions of the Academy. This calculation was not—at the Société de Physique—by many reasonable physicists; the principal one being that it was wrong, as it only considers H. Streater having drawn from it being that the more slowly the battery was discharged, the better the result, and in a general as opposed to a particular case. This is true of the ordinary batteries of the Plantè type, and of some primary batteries, as well as of dynamo machines. By using the battery very slowly, therefore, its duty is claimed to be 50 per cent., and as this proposition may be true of the Faure as well as of some other battery, the calculation of Mr. Tyler that the 220 lb. battery of 1000 foot-pounds of discharging energy per weight of battery could represent 14,750 foot-pounds stored up within the battery. This figure is, to a certain point, confirmed by an experiment made at the Société de Physique, where eight batteries, substituted, at a red lead during 1 hour 40 minutes, a platinum wire 12 in. long and .016 in. diameter, which required a current of 20 amperes to make the wire red hot. The battery gave up 252 foot-pounds per second, or 1,848,000 foot-pounds in all. According to M. Raynier, the weight of the batteries was 222 lb., so that the power stored up was equal to 12,541 foot-pounds per pound of battery. These cells have been a slight error here, because, as we have already seen, the useful weight of each battery was not 222 lb., but only 220 lbs., or 176 lb., giving a total of 1849 lb., or 10,910 foot-pounds per pound of battery could represent 14,750 foot-pounds stored up within the battery. This figure is, to a certain point, confirmed by an experiment made at the Société de Physique, where eight batteries, substituted, at a red lead during 1 hour 40 minutes, a platinum wire 12 in. long and .016 in. diameter, which required a current of 20 amperes to make the wire red hot. The battery gave up 252 foot-pounds per second, or 1,848,000 foot-pounds in all. According to M. Raynier, the weight of the batteries was 222 lb., so that the power stored up was equal to 12,541 foot-pounds per pound of battery. These cells have been a slight error here, because, as we have already seen, the useful weight of each battery was not 222 lb., but only 220 lbs., or 176 lb., giving a total of 1849 lb., or 10,910 foot-pounds per pound of battery.

According to the careful experiments we have made the useful storing power of the Faure accumulator battery is 11,250 foot-pounds per pound of battery, so that according to the different weights taken, the value of the latter to the former is 1.30, 1.06 or .55. This is a very long way off the 50 per cent. claimed by Mr. Tyler, and the difference between the two figures is not explained by the 252 foot-pounds per second, as the current must have been an exceptionally low one; then from which we had deduced his expectations had been furnished to him by M. Reynier. If this was the case, we know Plantè cells did but little credit to the renowned maker who supplied. Besides, as a matter of fact the batteries on experiment with were found to have been made by M. Plantè for sale (or rental), and other cases, and we have therefore understood that there are at present no Faure batteries ready for sale, the ones already produced having been made by M. Faure's own hands or under his directions, and it is only just to institute a comparison between the Faure battery made by M. Faure, and the Plantè battery made by M. Plantè.

The results which are given on another page to the exact we have mentioned, and for the reason why a battery in which the red lead is spread by hand, should be, weight for weight, superior to an apparatus in which the peroxide is obtained practically by electrolysis, and experiments can only confirm this deduction. The Faure battery is better adapted for industrial purposes, it is lighter and gives an answerer to most of the questions which we have put to it, but when compared with the Plantè battery it certainly, the Faure cell does not require a preliminary electrical process to render it fit to receive the charge, which is a very great advantage, and besides it offers greater resistance for an equal surface, while it is less liable to damage than the other apparatus, although the Plantè battery has been in existence about 20 years, and has undergone improvement as a secure of experience, is very neat and light, and for several very good reasons, of which we will mention one only—that of transport—which has been treated in the company's prospectus as a detail of insignificance, and referred to only as it were in an

STORED-UP ELECTRICITY.

THE current number of *La Journal Universel d'Electricité* contains some very silly articles by M. Fontaine. Already upon the Faure secondary battery, to which we recently referred (see page 548 ante). From this article we find the queen to make the following extracts: "The positive bearing the words 'Faure and Liglé' is enormous [sic] letters are still visible on the walls; the noisy articles that have appeared in certain journals have not yet produced, however, the bills are beginning to disappear, for the public slightly neat before the peroxide will form. The addition of a few crystals, with the help of which the decomposition and thereby charging might be prevented the apparatus from being influenced by accidental little further, would perhaps not as such accidents in the machinery. Mr. Sutton himself has done a good deal to bring us nearer this aim. In the long series of his investigations, which comprise respect probably, the right proportion between many different forms of cells, he first largely used lead and copper for instance, as the reduction at the negative electrode can only proceed with a sponge, as a special feature of which he claims that the simultaneous oxidation at the positive one. Consequently, a cladding his paper, Mr. Sutton remarks, that as this new method of conserving energy will have a wide field before it and benefit fellow-workers, he gives it freely without reservation and untrammelled by patent rights.



each face thus prepared a sheet of parchment paper is placed, and the whole is introduced into a sheath of thin leather. One plate is thus put on top of the other and rolled up, strips of rubber being introduced between the plates to keep them apart. The roll is then placed in a cylindrical lead sell, the outside of which is strengthened with copper bands, and the inside covered with red lead and lacker, so as to increase the useful surface of the battery. The latter then presents the appearance shown in the sketch, and one of the projecting stems from the lead plates is bent over and soldered to the exterior cylinder, which is ready for use when it has been filled with acidulated water, and the cover soldered on. The complete battery when charged weighs about 220 lb. It will be seen that this differs from the Plantè secondary battery only in the employment of red lead. The material chiefly employed in the same, the mode of construction is precisely similar. It must not be taken the part of the chief objection raised by M. Plantè; it has no merit in itself, to the contrary, it is a very great objection, as the red lead, after charging, is only useful to keep the red lead in place. It is, in fact, the red lead which constitutes the useful element, and gives the special advantage to the apparatus. According to the inventor there are two advantages gained. The long and delicate operation necessary to prepare the Plantè battery is not required. (This operation consists in alternately charging and discharging the cells when copper goes to one plate, and produces a thin layer of peroxide of lead, and hydrogen goes to the other plate). The second advantage claimed is that the battery has a storage capacity much greater than that of Plantè; this proposition, according to M. Reynier, being deduced from numerous experiments, forty times greater with equal weights of batteries. The first advantage claimed does not exist, and the second is not proved, as the practical inspection and tests. The second cannot be admitted, as will be seen from what follows. M. Hospitalier and myself were desirous to submit the Faure battery to precisely the same tests that we have made with the Plantè battery. To do this we first addressed ourselves to the proprietors of the Faure battery, and asked them to send us two batteries for trial; that they would not object to which, but only after some time. Since this communication we have been prohibiting from them. In the absence of these data, we will reason on the figures supplied, and the experiments made by the proprietors of the Faure battery before the

SECONDARY BATTERIES.

As bearing upon this animated and somewhat personal discussion which has been carried on during the last two months between M. Philippart, representing La Force et Lacombe's battery, and Mr. C. Vickmar, on the subject of accumulating batteries, we are requested to publish the following letter. It is the abstract copy of a communication from M. Philippart to Mr. Vickmar, and its truce is as much as possible, and these have not been obtained without trouble. M. Philippart was induced to describe the Plantè battery, which is the only secondary battery, other than that of M. Faure, M. Plantè having, since it was patented long ago anticipated what M. Faure has recently brought forward, and which has been received with so much popular excitement. He then continues: "We will now proceed to the Faure secondary battery. It is protected by two patents dated October 25, 1880, and February 9, 1881, respectively. The first patent refers to the formation of the plates of the batteries, one of lead plates laid on frames covered on both sides with red lead, and protected by leather, attached by means of lead rivets, an arrangement similar to the rectangular batteries of M. Plantè. The actual batteries are quit as such, being constructed as follows. Two sheets of lead are taken 7.87 in. wide; one of three plates is 12.02 in. long, and the other of two plates is 8.26 in. long, and 0.078 in. thick. Each plate is covered on both faces with a layer of red lead reduced to a paste by water, 1.76 lb. being spread over the larger plate, and 1.54 lb. over the smaller. On

"Yours faithfully,

(Signed) "H. PHILIPPART.

"M. C. Vickmar, 7, Station Garden."

We trust that both the inventors and the public will benefit by this alliance.

cause of scrupulous minuteness. In order to furnish a force equal to one horse power during ten hours, ten batteries weighing 165 lb. each must be employed. This is throwing out of consideration the fact that a part of the charge only can be utilised on account of the fall of the potential below the necessary point, which would take at least 15 per cent. off its utility. Making no allowance for this, and for the fact that the battery is never twice, that is to say, 14 lots of battery, would be transported daily, besides all the other expenses, for a motive of 10 horses a day; we have the reader to know its own conclusion. In fact, to maintain that this mode of electrical distribution is more economical than by wires, where they not be used, is to maintain that the present system of distributing gas is not better than the hauling of an enormous gasholder to several places, that is the reverse is always a considerable loss, and that it would be cheaper to substitute a horse-drawn system of water transport by means of isgeneral barrels. But this is a point we do not press. It belongs to commerce and to science, and this journal has nothing to do with money interests. But science suffers when these categories are thus blind. It seems away one, and the love of novelty, sensational, and exaggerated promises unfolded create the public mind to receive favourably almost undeveloped of a capricious nature; the public not having obtained what they looked for turn away and refuse to have anything to do with more modest but useful applications which are offered to them. Will it not be thus with the Faure apparatus? The experience obtained have much interest, the inventor mentions in his letter to the Academy of Sciences, especially for traction, for which the battery may have a special future. But why does not the inventor confine himself within the limits of possibility?

"Whatever future may be in store for it, we are at present inclined to it for having drawn special attention to the study of electrical accumulators. Since the announcement of the Faure accumulator, a number of new others in course of development, all of them more worthy and interesting, and all promising a useful though less sensational future.

"M. Reynier, at the last sitting of the Société de Physique remarked aptly that he did not ignore the relative imperfection of the apparatus at present invented, but both M. Faure and himself had been unable to complete them themselves before bringing them before the public, and he trusted soon to be able to offer far better results than those given by the apparatus of M. Faure. I should undertake no prediction for a day of existence to a himself undertake not pressing without restriction an apparatus of which I cannot acknowledge the electromotive; it is, in fact, a false position, and one which he would do better to avoid."

Engineering, Sept. 5, 1883.

STORED-UP ELECTRICITY.

In the current number of the *Journal Universel d'Electricité* we find a criticism of the recent utterances of Sir William Thomson in the *Times*, on the subject of the Faure accumulator. This criticism, which is by M. Frank Géraldy, we reproduce almost in extenso.

"If the letter that published in the *Times* on the 7th inst.) had been anonymous, or signed by any ordinary name, there would have been no occasion for noticing it, but the illustrious name and high authority of Sir William Thomson demand for it full consideration.

"Sir William Thomson, one of the founders of the directors of the Electrical Exhibition, has not yet had his subjected certain Faure batteries sent to him to exhaustive tests during the last three weeks. He has however only given a single number resulting from his labours. This is much to be regretted, for if Sir William Thomson were able to test the correctness of the figures put forward in France, we had hoped that Sir William Thomson would furnish a series of figures which would entirely clear up the question. A charge of 1000 kilogrammetres per kilo. of battery is announced. The battery contains, we know, 12·5 lb. of useful lead, so that the amount stored is 1177 foot-pounds per pound. This is practically the maximum claimed for the battery by the inventors. Every one is now agreed on this point and it has been sufficiently proved that the Faure accumulator can store up, say, 1500 foot-pounds per pound weight of lead. The experiments of Sir William Thomson show that the Faure battery has been shown to be only slightly less than that in the Faure, the ratio between the two being 1 to 1.25, so that the two apparatus are not very far divorced from each other in storing power. It appears, then, not a little singular that Sir William Thomson, who has been acquainted for the last twenty years with the Planté battery, who has studied it, and exercised in it the praise it justly merits, does not discover the full amount of its merit until the day that it is proposed to him under the title of the Faure battery. Evidently his attention was not powerfully attracted to this latter apparatus. It is still more striking that Sir William Thomson cannot, in his own experiments with the Faure battery, find any of the surprising results then performed by Professor George Barbaeni; now, for two years at least the Planté battery has been used in performing analogous work, and it is chiefly in view of this special application that M. Faure and other constructors in Paris make and sell their apparatus; for example, the Planté battery is employed in the Gramme machine-workshops, telegraphs, &c., made for working with the battery. Its application to the Arlanet electric and other trades may also be mentioned. All these go to prove that the Planté battery can be manufactured for many industrial purposes, and that the Faure battery possesses in the absence of the preparing process preliminary to charging, the one advantage which is of little value in practice. Sir William Thomson does not, however, furnish any conclusions to run away with him. He does not embrace the still proposals of carting power and light from town to house, but putting this proposition on one side he indicates the true function of the battery, that of acting as a regulator in a system of distribution by conductors. . . . The owners of the Faure battery have doubtless felt the necessity of an authorised support based on experiments of the kind made by Sir William Thomson, and the publication of Sir William Thomson; this is all very well, but it appears strange that in order to obtain a certain opinion, they were obliged to cross the Channel. We would have thought that there exist in France, electricians who could have furnished it. It is evident that Sir William Thomson takes a most lively interest in M. Faure's apparatus. Not only has he made experiments with it, but he has given it a second and certainly large one has been made of his letter, they appear in many of the English papers, they are reproduced very incorrectly translated in the *Figaro*, they are printed on fly-sheets and scattered broadcast, &c. He allows one of his collaborators, M. Batholley, to come to France after receiving him in his experiments, and who is now engaged in Paris testing his valuable assistance in improving the apparatus. Shortly after the publication of the letter of Sir William Thomson, and when the accumulator is highly appreciated. For we think without being sanguine, there might have been found in France men of equal value with Sir William Thomson, and whose for scientific progress is not less than his. Judging from appearances one might think that the reputation of the latter is highly of native ability, or preferred to avail it. Doubtless this is not the case, but it is to be regretted that the letter in question has great chances extra for from the realm of action, and veil their affairs with the mists of distance. They illustrate the Latin proverb of which La Fontaine gave the well-known translation,

"'De loin c'est quelque chose, et de près ce n'est rien.'"

Engineering, Sept. 5, 1883.

FAURE'S SECONDARY BATTERY.

The English patent for this electric accumulator and its applications is dated May 26th, and is immediately preceded by another patent for secondary batteries in the name of Mr. Swan, dated May 24th. Full descriptions of the Faure arrangements were however published in France and in our columns before the date of the English patent, a circumstance which may be of considerable bearing on the validity of certain claims put forth in that document. For, may have a considerable amount to patented after it has been explicitly described in the public press. With regard to the employment of the secondary battery in connection with electric lighting, we may mention that Mr. Rapieff, in a patent taken out in 1877, describes a plan for using this apparatus in connection with an electric lamp; and Mr. Edison, in 1879, patented a storage battery for electric lighting, composed of two copper plates immersed in a solution of sulphate of zinc, a combination due in the first place, we believe, to Professors Hosston and Thomson, of Philadelphia. The charging current decomposes this solution of sulphate of zinc, and deposits metallic zinc on one of the copper plates, thereby transforming it into a temporary Daniell element minus the sulphate of copper. When the charging battery is cut off, and the circuit completed, the zinc is oxidised and a polarisation current flows in the connecting wire until both copper plates are clean again, according to the latest report of Sir William Thomson a Faure battery of large size may be trusted to retain 70 per cent. of the original charge, and he says he has quite ascertained that accumulators amounting in weight to three-quarters of a ton will suffice to work for six hours at full uniform rate of one-horse power." Fifteen hundredweight is, however, a considerable weight, a weight which puts the portcrage of electric power from the house to house out of the question. Sir William therefore, points out that where economy of weight is important, as in driving tramcars, economy of energy must be sacrificed. But he considers it very probable that a car arranged to take in, say, 7½ cwt. of freshly charged accumulators, on leaving head-quarters for an hour's run, may be driven more economically by the electric energy then by horses. Meanwhile, we understand that M. Planté has organised a factory for the manufacture of his secondary batteries, which have the advantage of being chargeable by a dynamo-electric machine, whereas Faure's can only be charged by a voltaic battery. It was for this reason that Planté abandoned the use of red lead subsequently taken up by Faure. Planté's battery has been stated to accumulate only one-fortieth of Faure's; but the Count du Moncel estimates that, weight for weight, the electric capacity of the Faure battery is only 20 per cent. greater than that of the Planté.

THE STORAGE OF ELECTRICITY.

M. Faure's "box of electricity," known in scientific circles as a "pile secondaire," started even electricians not a little, and was among them for a time the engrossing talk of the hour. In the rapid strides we are taking in electricity, as in all other departments of science, it is not to be wondered at that efforts are being made to practically utilise each new discovery. Mr. Charles Brush, of Cleveland, Ohio, having for several years been engaged, simultaneously with M. Faure, in devising means for storing electricity, low now not only had his labours crowned with success, but appears to have surpassed his rival. The means by which Mr. Brush stores electricity is also different from that of M. Faure, the latter's procedure, as is well known, being based on the invention of Planté, several years prior. Mr. Brush may or may not have obtained results equal to M. Faure some years ago, as he claims to have done; what is of more importance is the fact that the details of the American invention are quite different from those of either of these French inventors, and do not infringe upon their rights. Although the full details have not yet been published, we are able to state that the storage recevoirs are metal plates capable of receiving a large charge of electricity, and of retaining it for an indefinite time. Being made of varying dimensions, and being quite portable, they may be sent around day by day, and delivered to the consumers from a waggon, in much the same way as milk, bread, and other necessaries of life are now supplied. If only one half of what Mr. Brush's friends say of his invention be true, the application of electricity in a convenient and economical manner to lighting, motive power, and to everything to which electricity is applicable, is now in a fair way of making a rapid approach. We are not of that those who know the inventor owe that he is a man who does not speak of his work until he is satisfied with it, and this is saying a good deal for the value and merits of the present invention. Some inventors talk too loudly and too big, or others do it for them, as we know from quite recent

Engineering, Jan 27, 82.

THE SUTTON STORAGE BATTERY.

The latest form of Mr. Henry Sutton's sulphate of copper storage battery has been described by him to the Royal Society. It consists of a flat square copper case or box, similar in shape to the earthenware pot of a Grove or Smee cell. This box is fitted with a lid of parchment wood, from which hangan plate of lead amalgamated with mercury. The lead is supported by being fixed in a groove along the underside of the wooden lid, and its lower end is placed in a corresponding groove along the upper side of a slip of parchment wood resting on the bottom of the cell. The lead plate, which is the positive electrode of the cell, thus forms a partial partition, nearly dividing the cell into two compartments, and presenting a face to each of the copper sides of the box, which form the negative electrode. A vent hole in the wooden cap allows the solution of sulphate of copper to be introduced, and also the state of the charge to be examined by inserting a glass rod and observing the colour of the solution.

e publish teresting to fortune to er, but to all ie materials sends. The Horses and he Erzberg, g since the

times of the Roman occupation and till to-day, the mountain has yielded its inexhaustible treasure. A fire in Eisenerz in 1618 destroyed unfortunately the documents which then existed, carrying back the iron manufacture as far as A.D. 712, and the documents still in existence do not go back further than the twelfth century, a date which —early as it is—is late in the history of the Erzberg.

In our notice of the summer meeting of the Iron and Steel Institute we gave as full particulars about the Erzberg, that we need not here recapitulate them. It will be sufficient to say that for centuries the workings on the mountain have been divided into two sections, the upper part belonging to the Vordernberg ironmasters, the lower to those of Eisenerz. The level of the narrow gauge railway, which takes the upper ore over the Prielsbichl to Vordernberg is very nearly that of the small level shoulder seen on the left slope of the mountain, near where the "Berghaus" is barely visible among the trees. The Vordernberg ore is brought up to this line by a water lift, and carried round the back of the mountain and over the pass to Vordernberg. The Eisenerz ore is brought down the face of the mountain, by the inclined plan shown in the drawing, to the calcining kilns, and thence down to the ore reservoirs, or direct to the blast furnaces.

The nineteen Eisenerz blast furnaces were united into the *Innerberger Hauptgewerkschaft* as long ago as 1625, but the wasteful system of isolated working existed among the fourteen Vordernberg works until so late as 1829, when all but one united their forces, this last only joining with the rest in 1871. The boundaries between the upper and lower workings were regulated carefully in 1871. The lower workings are now carried on by the *Alpine Montan-gesellschaft*, who also have some of the workings, along with several private owners, whose mines have been formerly mentioned. The total production of ore from the Erzberg was 128,700 tons in 1862, 359,040 tons in 1872, and had increased to 512,000 tons in 1882.

We are indebted to the courtesy of Herr Anton Jugovitz, the chief engineer of the Alpine Montan-gesellschaft, for the photographs of the Erzberg which we have reproduced to-day, and both to him and to Herr Kenitz, of Vordernberg, for much information—most freely and kindly given—about the works and workings in Styria, of which our readers have already had the benefit.

THE CHEMISTRY OF SECONDARY BATTERIES.*

Soon after the meeting of the British Association at Southampton, we gave an abstract of a paper read by Dr. Gladstone, before Section A, in which the author related his recent researches on the chemical reactions in secondary batteries with special reference to local action. Dr. Gladstone had ascertained that the local action which corrodes the lead plate supporting the peroxide of lead thus impairs the value of the battery, took place during the formation of the battery, during the repose and during the discharge, and that it therefore becomes an important question to determine what modification of the present arrangements would minimise, or if possible altogether prevent local action. Dr. Gladstone presumed that the sulphate of lead formed in the secondary batteries could be oxidised as well as reduced, to yield peroxide of lead in the former and spongy lead in the latter case, and thus

NEW MODE OF GENERATING ELECTRICITY.

Mr. J. A. Kendall, F.C.S., has discovered a reliable generator in using occluded hydrogen instead of zinc. The cell is constructed by using a tube of platinum foil closed at one end and connected with glass tubes, by which hydrogen is supplied to the platinum interior. The other element of the cell is an ordinary platinum crucible. Various substances are fused in the platinum crucible at a red heat, and by connecting both the platinum tube and crucible with a galvanometer, by means of platinum wires, a generation of electricity is obtained. Chlorides of the alkaline and earth metals in a fused state give a current; the hydrogen, after passing through the salt and walls of the crucible, is oxidised by the air. Vitreous matters, such as glass, give a better result than alkaline chlorides — even porcelain and earthenware transmitting the hydrogen at a high temperature. The effects were found to be reversible; and the quantity of electricity developed is proportional to the amount of hydrogen diffusing through the apparatus, or, in other words, to the metallic surface. It also increases with the temperature, but the electromotive force is very low. Mr. Kendall also found that the hydrogen made the vitreous substances conductive.

PRIMARY BATTERIES.

To the Editor of Engineering.

Sir,—I think that you have done good service to the advancement of the study of home-to-house electric lighting by the publication of the interesting article on Primary Batteries which appeared in your issue of the 11th inst. I, too, regarding my battery, to which you specially refer, I would ask your permission to make an essential rectification. Your reporter recently described it, by error, as a zinc-copper battery, whereas it is a zinc-platinum one. I send you herewith a few words to compare the action of my one-cubic-foot cells with those of a Daniell battery.

You allow that I am right in arguing that "Since a given metal will evolve different amounts of heat in entering into combination with different bodies, it will therefore be assumed at different rates in a battery producing a given amount of electric energy according to the combination which is employed." But you add that "what is that not an indication, in other words, that the consumption of zinc in batteries using different liquid electrolytes cannot be always a constant quantity?

In a zinc-copper battery the heat evolved by the combination of oxygen with a given weight of zinc is very considerably neutralised (as you have shown by the figures taken from Sir William Thomson's paper) by the heat of Mixing of the sulphuric acid, oxygen with the copper; but this does not apply to a zinc-platinum battery. We must therefore, by Sir William Thomson's reasoning, omit the negative quantity 180.0 heat units) from the action in my cells, leaving 7670 heat units instead of only 7850.4 as the thermal equivalent of the chemical action produced by oxygen on zinc standing in dilute sulphuric acid, and this is equivalent to a consumption of only 1.7 lbs. of zinc per horse-power per hour.

Again, the chemical action in my battery is mainly produced by the action of chlorine on the zinc, and thus Sir William Thomson's suggestion would commence with (1) the heat evolved by the combination of one gramme of zinc with chlorine, viz., 1917 units. If to that he should add (2) the heat evolved by the combination of 1 gramme of chloride of zinc, &c., the result as to the consumption of zinc per horse-power would be even less, and certainly closely approximate to Mr. Gaulard's observations.

But, Sir, I entirely agree with your observation that "it is not the cost of the zinc which has hitherto prevented the use of batteries." That can be recovered, perhaps even with increased value, in another form. The nature of the liquids, the unpleasant fumes, the polarisation and local action, and the cost of labour, are, as you say, the mechanical impediments of the cells, and, as you so justly remark, the main obstacles which have to be overcome before primary batteries can be applied as the useful auxiliaries in electric lighting which I have little doubt they may prove in days not far distant. In my battery I trust that I have made some slight progress in that direction.

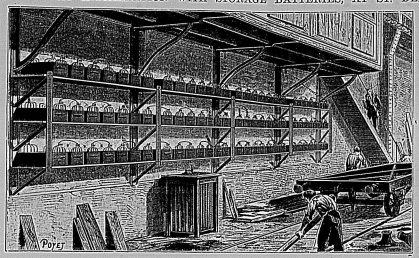
Yours, &c.,
W. R. Ll. Ross, M. Inst. C.E.

[The gist of our article was that the electromotive force of a given cell represents the resultant of the chemical actions within it, whatever they may be. As Mr. Ross says the nature of one of his solutions an entire secret we were obliged to refer to the Daniell battery as an illustration of our meaning.—Ed. E.]

ELECTRIC LIGHTING AT ST. DENIS.

Although electric accumulators have fallen very far short of the sanguine expectations of their original inventors, and the confidently expressed anticipations of those who make it a business to sell inventions to the public, experience has shown that within yet unknown limits they are useful auxiliaries to dynamo-electric generators. These latter can be employed in the direct production of light during the hours of normal requirement, while during the rest of the day they are used to charge the accessory batteries for feeding incandescent lamps when desired. This mode of electric lighting, which enables the highest duty to be obtained from the generating plant, has hitherto been rather talked of than realised, and for this reason the first industrial application of the method, inertia a somewhat detailed description. A notice of the installation has already appeared in some of the French scientific journals, and some of the data now given are obtained from them, the remainder having been given by the engineer in charge of the work. The installation we are about to describe has been made for a number of Weston lamps, and of Maxim incandescence lamps, and it has been carried out by M. Denis Labarre for the Compagnie d'Eclairage Electrique (the latter transformed Jablochkoff Company), who own, under Weston, Maxim and other patents for France. The Compagnie Parisienne du Gaz et Electric at St. Denis is principally occupied with the manufacture of railway rolling stock. The works include, therefore, large stores of seasoned timber, sawmills, and painting shops, which, more than most other factories, demand constant surveillance to avoid fire. For this reason lighting by gas, or by oil, becomes very dangerous, while, properly carried out, electric lighting is quite safe. The directors of the company desired to utilise to its maximum the power available for obtaining as much lighting power as possible. The engine at the works does not develop more than 60 effective horse-power, of which about 45 are absorbed by the various machines, tools, &c., leaving 12 horse power free for electric lighting purposes. Under these circumstances it was not possible to maintain more than 30 arc lamps, which are kept going nightly by a Weston machine. These lamps work under the conditions indicated in the recent report of M.M. Cabel, Joubert, Le Blanc, Pathier, and Tyrrel. We may recall here that that report mentions that the experiments made on a Weston machine feeding 10 Weston lamps, were remarkable from the extreme regularity of the arcs. It points out also that for an effective work of 13 horse-power, the lamps gave a horizontal luminous intensity of 92 carcels, and a maximum intensity of 101 carcels. By employing reflectors to economise the light, it was stated that the intensity of illumination of the lamp may be increased to 160 carcels. Used as they are in this place to the Weston system, which has been already very fully described in this journal (see pages 501 and 572 of our last volume). It will be sufficient to state that in the installation now being noticed the generator is driven at 900 revolutions per minute, producing an electromotive force of 250 volts, and a current of 30 ampères, conditions somewhat inferior to those recorded in the official report, so far as concerns the available electromotive force.

ELECTRIC LIGHT INSTALLATION WITH STORAGE BATTERIES, AT ST. DENIS.



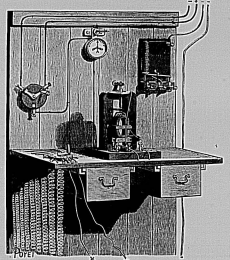


Fig. 1.

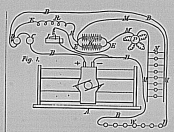

Fig. 3.

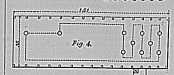

Fig. 4.

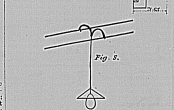

Fig. 5.

During four hours each day the Weston generator is employed to charge 80 accumulators of the Kabath corrugated type, placed about 250 yards from the generator and connected to it by insulated overhead conductors. These accumulators, arranged in two series of 40 each, are able to supply each day during the period of lighting required—about three hours—the current necessary to feed 30 Maxim incandescence lamps distributed over the painting shops and drying sheds. The brushes of the Weston generator can be easily shifted in position with reference to the collector, and the intensity of the current can then be varied within certain limits. But for charging the accumulators it was requisite to easily diminish it still further, and to adopt an arrangement by which the current could be caused to pass to the lamps or to the batteries, without endangering one or the other. With this object no less wire resistance is introduced into the charging circuit, so that the electromotive force may be diminished. Moreover, in this same circuit there is an automatic current breaker. If the electromotive force of the accumulators becomes higher than that of the generator, the batteries would commence discharging; this would be likely to occur, especially at the instant of starting the generator, when the current from the accumulators would reverse the direction of the electro magnets of the generator. The annexed diagram, Fig. 1, shows the general grouping of the machines, accumulators, Weston, and arc lamps. In the diagram A is the dynamo machine; B, the circuit for the arc lamps W; indicated in galvanometer C; and a two-way commutator D. During the day the key of this commutator is set so as to place the generator in connection with the circuit B, E, G, which comprises the 24 Kabath accumulators E E; G, the resistance F, and the automatic circuit breaker K, the resistance F, and the automatic circuit breaker K, the resistance F, and the automatic circuit breaker K

DEC. 30, 1881.]

A NEW STORAGE BATTERY.

In a paper read before the Royal Society on December 15, Mr. Henry Sutton, of Ballarat, Victoria, gives an account of some experiments which have led him to the construction of a new secondary battery for storing electricity. One important fact discovered by him is that the storage in lead cells is facilitated by amalgamating the positive lead plate with mercury. One of his guiding ideas was to employ as a negative plate a metal whose oxide should be soluble in the solution, and could be reprecipitated from it. With amalgamated lead as the positive plate, he employed negative electrodes of zinc, iron, copper, the solution in each case being a salt of the metal composing the negative plate. All gave good results, but the best was obtained from an amalgamated lead plate for positive electrode, and a copper plate for negative immersed in a solution of sulphate of copper. The two sheets are perforated with a number of holes, then rolled in a spiral, separated by rubber bands cut every 5 in.; the holes in the plates and cuts in the bands being to allow free circulation of the liquid. The chemical action during charging is that the oxygen of the decomposed solution combines with the lead, forming an even coat of the insoluble peroxide, and the hydrogen replaces the copper of the solution, leaving the copper deposited on the negative plate. During discharging the peroxide is again reduced, and the copper deposit oxidised, the copper combining with the acid and forming cupric sulphate. The power of the cell is considerable, and it is said to be very constant. It can be made to keep up for hours, the time being dependent on the quantity of cupric sulphate decomposed. By the decomposition and recomposition of one pint of cupric sulphate, Mr. Sutton has obtained over two hours' effective work by heating to a red heat 1 in. of No. 28 iron wire; the coil measuring inside 4 in. deep and 4 in. in diameter. Free crystals of sulphate of copper in the cell prevent the oxidation of the amalgamated lead plate, as the solution should be slightly acid ere the peroxide will form. The No. 28 cell is large enough gives out a peculiar rattling noise, which may be due to the deposition of the copper on the negative electrode altering the form of the spiral. Mr. Sutton constructs a practical form of the cell after the model of Cruikshanks' trough battery, the space between the pairs of plates being filled with the solution. A current of tension sufficient to overcome the contrary electromotive force of the series is used to charge the battery, when the positive plate becomes peroxidised, and copper is deposited on the negative plate. With two boxes of twenty-five plates each, charged by thirty Bunsen cells, very powerful currents are obtained. A number of twenty-five of plate boxes can be coupled in quantity during the charge, and in tension during the discharge. Twenty of such boxes one foot square insulated by measurement will give in series a battery of 500 jairs, one foot square area. It should be stated that Mr. Sutton has taken out no patent.

VARLEY'S CONSTANT BATTERY AND CONDENSER.

At the last meeting of the Society of Telegraph Engineers and of Electricians, Mr. Cromwell F. Varley, F.R.S., described a form of Daniell cell patented by him so far back as 1854 (No. 2055), though strangely enough this patent has been so far ignored that, according to Mr. Varley, the cells which he describes have been repatented three times, namely, by the late Sir Charles Bright, Meritt, Minotti, and by Marie Davy. The cell introduced by Mr. Varley to the meeting consists of a glass vessel in the bottom of which is placed a flat cylinder of sheet copper, having its upper part covered with holes. This is filled with crystals of sulphate of copper, and an electrode runs from it to the outside of the cell. In the mouth of the cell is suspended a conical hank of zinc wool, well amalgamated by mercury and having an electrode attached. The conical shape is given to serve the double purpose of allowing the hydrogen gas which is evolved at its surface to rise more freely upward than in flat plate would allow, and at the same time of allowing the metallic copper deposited on the plate to drop more freely off. A solution of one volume of sulphuric acid to one volume of water is the exciting liquid employed; and a layer of porous matter, such as burnt clay, is spread over the drilled hole in the cover of the copper vessel containing the crystals of sulphate of copper. These crystals dissolve in the liquid and thereby render it heavier than the purer acid solution above. The result is that it tends to remain at the bottom of the cell by its own weight, although this does not prevent diffusion of the copper salt upwards. To prevent the latter as much as possible from reaching the zinc, a syphon is occasionally inverted in the cell to draw off a portion of the liquid below the zinc, and its place is supplied by fresh acid solution. The amalgamation of the zinc, according to Mr. Varley, insures that the latter will keep the potential due to zinc, however its surfaces be contaminated by copper or any other metal. Mr. Varley then described the sulphate of mercury battery, which he asserted as his 1854 patent, and which distinctly anticipated the well-known Marie-Davy cell. It is interesting to note, too, in connexion with this patent, that the use of induction surfaces for storing up electricity for telegraphic and electric lighting purposes is therein claimed. Mr. Varley is a far-sighted inventor, and though the induction surfaces he intends are what in known now as condensers and not "secondary batteries," such as those of Plantè and Faure, it is plain that he foresaw some of the services which accumulators of the electric current would render in electric lighting. The induction surfaces were designed by him to "store up the power and so make a small battery answer the purposes of a large one, and also to act as a measure when telegraphing through long submarine cables." They were composed of sheets of tinfoil separated by sheets of oiled silk, gutta-percha, or other nonconducting substance, and alternate foils were connected to opposite poles of the battery. Their use in submarine telegraphy is now universal, and they have also been employed by Jaibolckkoff and others in electric lighting.

RECENT IMPROVEMENTS IN GALVANIC BATTERIES.

THE greatest of invention in connexion with electric batteries is apparently moving at a very slow rate at present, and so far no one has yet invented a battery which will enable us to light our rooms as cheaply as by gas or paraffin lamps. Amongst recent patents we notice one recently granted to Mr. H. C. Jaeke for an invention in cells and batteries of the kind which carbon, in the form of highly burnt coke of petroleum or wood charcoal, and in the shape of small pieces, is employed in connexion with zinc, being separated from direct contact with the zinc plates by an absorbent diaphragm. Salts of potassium, sodium, or ammonium are used as the electrolyte. The zinc or zinc electrodes are made in the form of plates, and are set on wooden blocks surrounded by a trough of thermometer, which allows the liquid to penetrate to the pieces of carbon in which the zinc or iron cells are imbedded. Hereafter form the patentee coils long strips of copper and zinc on a loom of wood, and separates them by interposing pieces of indiarubber. The wheel or disc thus formed is received by an electromotive, so that the cavities that does not cover more than half the disc at any one moment. Another device, which, however, went no further than the stage of preliminary invention, is the invention of Mr. L. Hartmann, and is thus described: "I employ as the exciting liquid caustic potash or caustic soda in solution, and for the positive electrode I use a mixture of peroxide of copper, which I employ either first, copper oxide, cobalt, nickel, or silver, or gold. By preference I employ silver, and I use the form of network, also cast in combination with fragments, or of fragments alone, although network is preferable, or I use any leaky, organic or inorganic, sheet in the form of network coated with silver by the electrolytical process. I construct the outer cell of a flat shape, like a shallow pan or a plate. I put in the bottom of this I place the zinc by preference in the form of strips, either rolled spirally or otherwise arranged so as to offer considerable surface. Upon the zinc I place a porous diaphragm of cotton-wool, textile fabric, or other suitable material, so arranged as to entirely separate the lower part containing the zinc from the upper part containing the negative plate, and I place upon the diaphragm a plate of negative electrode formed by pressing a mixture of peroxide of silver or iron, or any other form may be used, preferably considerable surface and which is immersed in or nearly dumped by contact with the exciting liquid in which the zinc is immersed."

A more important device which has been fully patented by Mr. J. Boyd, consists of improved elements and improved arrangements. This he proposes to increase the surfaces of carbon electrodes by preparing them from comparatively thin sheets of carbonised and suitably treated organic substances, such as cellulose, perforated or grooved, or heat into zigzag, spiral, cylindrical, or other forms. For the same purpose he uses rods or groups of comparatively thin pencils or rods of carbon, such as gas retort carbon, coke, or charcoal, or graphite, or any form of artificial carbon. These rods may be put up singly or together, or separate with a space between them, all being of course united or metallically bound together so as to make one pole. For the same purpose he uses carbonised organic fibrous substances, such as wood or cotton, flax or hemp, or threads or strands twisted or not, together or separately, or tulle, bobbinet, muslin, canvas, net, lace, and other similar woven or textile materials. These materials may be used separately, or combined with these above mentioned, and in the form of thin rods, sheets, ribbons, threads, or any other suitable form, and grooved or perforated as may be desired.

He states that these substances more strength, elasticity, rigidity, and more particularly electrical conductivity, the patentee carbonising them under necessary pressure and at proper temperatures in closed vessels in presence of carbonifierous or hydrocarbons elsewhere at suitable pressure, or in presence of liquid or solid bodies of the same substance, or in presence of a current of the same, so as to obtain upon them a deposit of the particles or granules of crystalline or metallic or graphitoidal carbon. To decrease the conductivity they may also be covered with thin layers of one or more metals, such as platinum, palladium, lead, indium, silver, &c. The principal aim of these arrangements is to obtain electrodes having a large surface, every part of which is thoroughly connected with the body of the battery. By virtue of such arrangements the patentee says there is a decrease of the local action and depolarisation of the force of polarisation of the electrodes, their connection with the liquid or solid depolarising agent is increased and more intimate, and consequently the conductivity of the current given by the battery is increased.

In the new forms of improved cells which the patentee proposes to construct, he takes lead or other metal for one electrode, solid peroxide of lead or peroxide of manganese, or acid, and, in forming one or more sheets, rods, grains, ribbons, or formed into a vessel. Peroxide or oxides of lead, barium, manganese, silver, iron, copper, or their equivalents, are separately or combined, or mixed with small pieces, roughness or cuttings of lead, shot, pierced or granulated lead, or other metal of which the electrode is made, or carbon or graphite, or other material for the above-mentioned electrode to form a porous vessel, which may be afterwards closed or sealed, leaving apertures for the escape of the gas and the charging and discharging of the cell.

This porous vessel he puts into another vessel of larger size, which may be zinc or other metal, or mineral electrode, and into which he puts another electrode made of zinc, or the large vessel may itself be made of zinc. An exciting liquid or liquids for the charging of this cell he proposes to use a solution of the salts or hydrates or oxides of zinc, ammonia, potassium, sodium, or other alkali metals, ten solution also salts separately or together with the above-mentioned solution. Another liquid he proposes to use is that of chromic acid, but in this case he prefers to use solutions of hydrates of alkalies, hydrochlorides of alkalies, potassium, or other alkalies metal, or solutions of sulphuric, hydrochloric, nitric, or other acids, separately or together. The battery with peroxides or oxides of lead, iron, silver, manganese, a solution of salts, such as chloride, chlorate, permanganate, sulphate, nitrate, carbonate of ammonia, sodium, potassium, or magnesium. Or the said battery may be used as a double liquid battery. Thus for negative cell or vessel where there is electrode of carbon, lead, or other metal with peroxides or oxides of lead, iron, copper, silver, and not manganese and depolarising liquid to be used a rather strong solution, say about 20 per cent. of sulphuric, hydrochloric, chromic acid, or nitric acid, and in this other or positive vessel or cell he puts the zinc in a solution of zinc or several of the salts of zinc above-mentioned, suspension, or other alkalis, separately or a solution of sulphate of zinc. Also as an extra liquid in the negative cell with the said substances, including oxides and peroxides of manganese, a solution of hydrosulphate of ammonia or alkaline metals.

With reference to the new exists of copper battery of Messrs. Lalande and Chaperon, patented on the 5th, 31, Hospitalier gives the following account of a trial made with a cell weighing 1,014 grammes, and containing 250 grammes of oxide of copper, and 500 grammes of a solution of caustic of potash at 40 per cent. The E.M.F. of the cell at first setting up was 0·98 volt, and the cell was able to maintain this for seven days through a resistance, the current thus supplied was, on an average, half an ampère during six days, or 518,400 seconds. The total quantity of electricity supplied was 259,000 coulombs, the weight of the consumed 88 grammes, which corresponds to a theoretical production of 259,000 coulombs. This, says M. Hospitalier, is a most important point, and very favourable to Lalande and Chaperon's battery, for it shows that the local action is practically nil. The energy that the battery is capable of supplying is, therefore, available at will, without any other necessity to disturb the circuit in order to withdraw the zinc from the liquid, as in the indicated case of potash batteries, for example. The useful available energy is 0·92 kilogrammetres.

per account. In my case, therefore, the battery supplied 10,368 kilogrammetres of available electrical energy. This exceeds the results obtained up to the present with accumulators of the same weight: but we must add that the supply is much slower than these latter. It is, however, easy to increase this rendering by increasing the surface of the elements and by diminishing the distance of the oxide from the zinc plate. The capacity thus increases more rapidly than the weight, and we may approach that of the accumulators. The normal constancy of the resistance of the liquid is attributed chiefly to the fact that the product of the reduction of the oxide of copper, which is a good conductor, and that the solution of an alkaline salt of zinc which is formed presents a conductivity almost equal to that of the solution of potash. For a given weight of zinc dissolved, about three times the quantity of salt of potash is required, and a quantity of oxide of copper, equal to 1·25 times the weight of the zinc.

SOME RECENT IMPROVEMENTS IN GALVANIC BATTERIES.

THE records of the Patent Office show that great efforts are made by inventors to provide "cheap, handy, and powerful" galvanic cells, as well as secondary batteries. Whether any of them will suit the time-honoured standard will have to be proved, but we give here descriptions of a few for the benefit of those who are inclined to experiment in this direction. Messrs. Holmes and Rossiter patent cells in which granulated lead, either in powder or cakes, is placed in a porous pot, and so separated from a zinc or lead positive electrode, the electrodes being interchangeable as regards their position. In another form the negative electrode of platinum or carbon is packed around with a mixture of metallic peroxides, such as those of lead or manganese, and the zinc or positive electrode is mounted in a porous pot. This form may be modified by making the pot itself of a material filling it with a mixture of metallic peroxides and some inert substance. In another form the zinc or positive electrode is packed between the outer vessel and the inner porous pot, while inside the latter is a mass of carbon granules, scraps, or plates of zinc. The rods or plates of peroxide of lead may be surrounded by coiled zinc wire, or strips of zinc, the two electrodes being separated by wood strips. In another form an electrode of carbon is prevented with the metallic peroxide by exposing it to the action of gaseous chlorhydride, then impregnating with the salt, which is afterwards decomposed by heat or chemical reaction. The zinc electrode may also be built up of layers of perforated zinc sheets. That cell is also described in which *in situ* specification shows an advantage of the present Patent Law.

Mr. G. U. D. Ross has also patented an improvement in the ordinary combination of zinc and carbon, in which the carbon-rod is packed round with broken coke. In the zinc compartment is the exciting solution in a 1 per cent. solution of hydrochloric acid, and in 2 per cent. solution of hydrochloric acid is placed the carbon cell in a mixed liquid composed of 1 volume of hydrochloric acid, 3 volumes of sulphuric (or hydrochloric) acid, and 4 volumes of water. The patentee also mentions nickel-plating, instead of amalgamating, the zinc.

M. G. G. Shrimpton, of Paris, has also patented further improvements. He covers a carbon plate both sides with chloride of silver, and immerses it in a solution of hydrate of potassium or sodium, the hydrate being in the proportion of 30 to 40 per cent. of the weight of the water. A plate of zinc is immersed in the same solution close to the carbon, which may, however, be wrapped in asbestos cloth or placed in a porous cell. The battery may be revivified by plunging the carbon plate in a bath composed of nitric acid and hydrochloric acid, or chloride of sodium dissolved in water, or chlorochromate of potassium and nitric or sulphuric acid, the object being to chloridise the metallic silver. The hydrates may be dissolved in glycerine if the battery is exposed to frost.

Amongst portable batteries may be noted one recently patented by Mr. J. MacGovin, which is a modification of the chloride of silver arrangement. A short piece of copper tube has one end closed by a plug of the same metal, and, the interior being coated with silver, is subsequently covered with a layer of fused chloride of silver; the other end of the tube is closed with a cap of some insulating material through which passes a zinc screw, holding in the centre of the tube a cylinder or tube of zinc, extending nearly to the bottom of the cell thus formed. The exciting liquid is sodium chloride (common salt), or sulphate, or zinc chloride. The wires are attached respectively to the zinc screw and to the exterior of the copper tube.

M. E. Hunt's peculiar battery, which consists of a bath of melted nitrate brought into contract with heated coal, carbon, is described in specification No. 4276, 1882. We think it is of interest only from its singularity.

THE STORAGE OF ELECTRICITY.

THIS change of electricity is a subject which naturally attracts great attention at the present time, which may without much exaggeration be described as the talk of electric circles, and thanks to the letters of Sir W. Thomson, the public has been led to believe that a great and wonderful discovery has been made, which is to give us light, power, and heat for next to nothing. The statement that a million foot-pounds of energy had been stored in a box and conveyed from Paris to Glasgow seems to have astonished the newspapers, especially the supposed magnitude of a "million foot-pounds." Those acquainted with the rudimentary data of mechanical science know that large as a "million foot-pounds" looks upon paper, it really represents very little in the shape of power—just about as much for instance as one little gas-engine would give out at the cost of one halfpenny! The really important point is that M. Gaston Planté and Faure, experimenting on the lines laid down by M. Planté, have invented a modification of the chloride of silver arrangement, by which pieces of copper tube can be coated by a plug of the same metal, and, the interior being lined with silver, is subsequently covered with a layer of fused chloride of silver; the other end of the tube is closed with a cap of some insulating material through which passes a zinc screw, holding in the centre of the tube a cylinder or tube of zinc, extending nearly to the bottom of the cell thus formed. The exciting liquid is sodium chloride (common salt), or sulphate, or zinc chloride. The wires are attached respectively to the zinc screw and to the exterior of the copper tube.

M. E. Hunt's peculiar battery, which consists of a bath of melted nitrate brought into contract with heated coal, carbon, is described in specification No. 4276, 1882. We think it is of interest only from its singularity.

THE STORAGE OF ELECTRICITY.

THIS change of electricity is a subject which naturally attracts great attention at the present time, which may without much exaggeration be described as the talk of electric circles, and thanks to the letters of Sir W. Thomson, the public has been led to believe that a great and wonderful discovery has been made, which is to give us light, power, and heat for next to nothing. The statement that a million foot-pounds of energy had been stored in a box and conveyed from Paris to Glasgow seems to have astonished the newspapers, especially the supposed magnitude of a "million foot-pounds." Those acquainted with the rudimentary data of mechanical science know that large as a "million foot-pounds" looks upon paper, it really represents very little in the shape of power—just about as much for instance as one little gas-engine would give out at the cost of one halfpenny! The really important point is that M. Gaston Planté and Faure, experimenting on the lines laid down by M. Planté, have invented a modification of the chloride of silver arrangement, by which pieces of copper tube can be coated by a plug of the same metal, and, the interior being lined with silver, is subsequently covered with a layer of fused chloride of silver; the other end of the tube is closed with a cap of some insulating material through which passes a zinc screw, holding in the centre of the tube a cylinder or tube of zinc, extending nearly to the bottom of the cell thus formed. M. E. Hunt's peculiar battery, which consists of a bath of melted nitrate brought into contract with heated coal, carbon, is described in specification No. 4276, 1882. We think it is of interest only from its singularity.

galvanic cell capable of decomposing the dilute sulphuric acid, or practically of liberating hydrogen and oxygen, the reservoirs of the gas battery become replenished. It is not unlikely that, before long, a useful secondary battery, working on the principle of the Grove gas-battery, will be invented; but the latter is practically of little use as a reservoir of electricity, and just at present no more encouraging results in the direction of storing electricity have been obtained with the modifications of the durieux which Jüttner was the first to employ. About 20 years ago, M. Gaston Planté took up the study of the subject where Jüttner had left it, and after experimenting with a number of metals, he found that electrodes of lead immersed in dilute sulphuric acid gave the best results. He, in fact, invented the first real accumulator of electricity—a cell which, charged by a weak source, would yield a powerful current for a short time. The Planté cell consists of two sheets of lead, cut so as to leave a long tongue projecting at right angles at the end of each; these are separated by two sheets of canvas, and are rolled up loosely, so as to fit into a battery-jar containing dilute sulphuric acid. The canvas is merely for keeping the two sheets of lead from touching; bands of rubber and other materials have also been used, felt, for instance, being employed in the Faure battery. The lead plates being connected with an ordinary battery, oxygen and hydrogen are liberated, the former attacking the surface of the plate and forming peroxide of lead, while the hydrogen, at first probably to a great extent occluded by the other plate, the surface of which becomes a peculiar spongy texture. When the plates are brought to this state the secondary battery is fully charged and ready to receive a charge, and in the shape of electrical work done will store up a considerable amount of energy which it will give up again in the form of electric current, less a certain percentage. The current furnished by the secondary battery is, as a rule, far more intense than that employed to charge the accumulator; for instance, a battery of half a dozen Planté cells, about tin, high, may be charged by a couple of Bunsens, and when, so to speak, saturated, will yield a current capable of melting a knitting-needle, or of producing a brilliant electric arc for a time, counted by seconds rather than by minutes. A reference to the indices of our back numbers will show that a form of secondary battery have been devised, but practically, M. Planté's is the most successful. In the exception of the most recent modification by MM. Reynier and Faure. Instead of charging and recharging, including reversing the action, in order to get the lead plates into the proper condition for receiving the charge, M. Camille Faure coated the plates at once with a film of minium or red-lead, the ordinary compound of which is represented by the formula, $2\,PbO,PbO_2$, whereas the peroxide formed by the charging and recharging of the Planté battery is PbO_2. The plates so coated by layer of felt or rubber are rolled up just as are those employed in the Planté batteries, and according to the accounts published in Paris, the results are surprising. There seem to be no doubt that the use of the red-lead or minium is a decided advantage—to what extent is not at present known, and that therefore the Faure modification of the Planté accumulator is more likely to be useful than its predecessor. It must be clearly remembered that the Faure battery creates nothing; it is a receptacle for electric energy, which it stores in the shape of chemical work, and gives out again in the shape of electric current, with more or less of loss—how much remains to be seen.

Referring now to the famous letter that appeared in the *Times* (see p. 231), and taking the statements there given by an enthusiast—a box containing four of the new batteries, each about 40in. in diameter by 30in. high, weighing some 70lb., and holding nearly one million foot-pounds of "power," conveyed to Glasgow in 72 hours —we may well ask what is the fact that has been made so much talk and paper to be wasted? The new battery enables us to "store electricity" in such a form that we can use it just when we want it; it enables us, therefore, to use electricity where before the invention of the accumulator we could not conveniently or comfortably employ it as agency; but as a source of power, from an economical point of view, the secondary battery is practically nowhere. To utilise it as power we must have a Gramme-machine, and that costs rather more than a gas-engine, while at the same time rather more than a million foot-pounds could be put into a box having a capacity of a cubic foot, in the shape of the common, well-understood, and cheap coal-gas. It is pointed out that the wonderful box pondalened no more energy than exists in an ounce and a half of coal; but then, unfortunately, we have never been able to utilise more than about one-tenth of the energy of the coal, whereas from the experiments of Sir W. Thomson it seems probable that we may fairly count upon recovering some 90 per cent. of the energy put into a battery, and it is obviously less many applications where lumps of coal would be simply useless. But the Faure battery weighs 60 times as much as its actual mechanical equivalent in coal, or 30 times as much as the theoretical equivalent. Suppose, then, we find some means of utilising the energy of coal in a more economical manner, as compared with the theoretical value; where then is the wonderful battery which, according to Scottish specialists and newspaper scribblers, is to revolutionise the industrial world? As the accumulator, to obtain the energy practically available, has to cost as much as coal, we must have 40 tons of coals, we must have 40 tons of lead plates and battery jars, and all these have to be detended, whether it is more convenient to use an electric current, or employ the more familiar appliances of steam or gas-engines. The Faure accumulator is large under these, say, a Daniell's battery, because it has to be used to employ the current generated by the latter under more favourable circumstances—under conditions in which a Daniell's battery would be useless. In fact, it is practically but another method of storing energy, and if the conditions of work are adopted to insure economy it will do that with a loss of only 10 per cent. of the energy imparted to it. Accumulators weighing three-quarters of a ton (16 cwt.) will work for six hours on one charge at the uniform rate of one horse-power, giving a high economy, probably fully 90 per cent. of the energy put into them; but if applied to driving tramcars, where it is necessary to reduce the weight to 5 cwt., Sir W. Thomson thinks that accumulators weighing 7½ cwt., and

PRIMARY BATTERIES AND ELECTRIC LIGHTING.

In a recent lecture delivered in the hall of the Society of Arts, Mr. J. Probert entered into the relative cost of dynamo and battery lighting. He took as the basis of his calculation a house lighted by 100 incandescent lamps each requiring 1 electrical h.p. and as electromotive force of 100 volts. Each lamp would therefore require 75 watts, and the whole 7500 watts, or 10.05 horse-power. Supposing the dynamo to have a commercial efficiency of 80 per cent., then the actual horse-power required would be 10.05 × 1.25 = 12.55 horse-power. A horse-power requires in the steam engine a consumption of 4 lb. of coal per hour = 50 lb. Therefore 50 lb. of coal would be required to generate the 12.55 horse-power, and this would be coal. Assuming that the lamps were to be alight to burn 1000 hours a year, or five hours a day, the annual cost of coal would be 65l. The price cost as of a suitable dynamo and engine with boiler would be, say, 700l., the interest on which at 4 per cent., would be 12l., and the annual depreciation would be 10 per cent., or 70l. The cost of attendance would be 60l., so that the prime cost would be 200l., and the total annual cost 147l., or 1l. 9s. 6d. per lamp.

On the other hand, with a voltaic battery the energy would require to be produced at a rate between 25.05 and 30.1 horse-power, since the efficiency depends on the ratio between the internal and external resistance of the circuit. Supposing the ratio to be such that the efficiency is 80 per cent. To liberate a horse-power of energy a quantity of zinc must be oxidized equal to 2.022 lb. divided by the electromotive force of a single cell. The highest electromotive force obtainable in a single saturated cell battery is 2.248 volts, but from this must be taken the energy absorbed in depolarization. The amount of reduction depends on the nature of the depolarizer; with nitrate of soda or sulphuric acid it is .708 volt, with bichromate of potash it is .943 volt, with fuming nitric acid it is .794 volt. Assuming that the latter is the depolarizer the net electromotive force would be 1.454 volts, and this corresponds, by the above rule, to a consumption of 1.39 lb. of zinc per horse-power hour of energy. To liberate 12.55 horse-power-hours, 12.55 lb. (say 13 lb.) of zinc must be used. The price of zinc is taken at 21l. per pound, the zinc used per hour costs 2s. 8¼d.; but the expense does not end here. Sulphuric acid, the usual oxidizer of zinc, costs 2d. per pound. To oxidize a pound of zinc 1½ lb. of sulphuric acid is required ($Zn + H_2SO_4 = ZnSO_4 + H_2$). To oxidize 13 lb. of zinc requires 19½ lb. of acid, and this costs 3s. 3d. This added to the cost of zinc makes 5s. 11½d. To give the best return the electromotive force must be high, and if we suppose the nitric acid produces N_2O_4, the amount of acid required is shown by the equation $2\ HNO_3 + 3\ H_2$ (equivalent to $3\ Zn$) $= N_2 + 3\ ZnO + H_2O$. It follows that the solution of every pound of zinc is accompanied by the dissolution of ⅓ lb. of nitric acid. In the production of 12.55 horse-power-hours of energy, 8½ lb. of nitric acid will be dissolved, the cost of which at 6d. per pound is 4s. 4d. This added to the cost of zinc and sulphuric acid gives 10s. 3½d. as the cost of materials. Neglecting the waste due to scrap zinc and partially spent solutions, this rate for 1800 hours per year amounts to 740l. 10s. for cost of materials only. The prime cost of the battery would be 120l., the interest on which at 4 per cent. is 5l., and the annual depreciation at 10 per cent. is 12l. Neglecting cost for attendance, we get a total of 759l. 10s., or at the rate of 7l. 11s. 8d. per lamp, as against 1l. 9s. 6d. for dynamos.

Mr. Probert considers rightly enough from these figures that for a large installation batteries are out of the question as compared with dynamos, at least until they are greatly improved; but for small installations, where dynamos are unsuitable (and there are many openings for such) the battery has a future before it. The use of lead or iron in place of zinc, or some cheaper oxidant than chromic acid, may considerably reduce their cost; and the utilizing of waste products, a subject which Mr. Probert yesterday spoke of in little moment, may effect still further economy. "It may be interesting to notice," said Mr. Probert, "that in the Telegraph Department of the Post Office, no money is ever thought worth preserving, except the 'black mass' (technically so-called) from the Daniells, which contains a very large percentage of pure copper in the metallic state. Last year there were 30,322 Daniell cells in use, and the sum realised by the sale of the copper as 'black mass' was 1,200l., or rather more than 4d. per cell per year. An idea may be formed from these figures of the magnitude of the sum likely to result from the sale of the zinc residues—which in the Post Office are thrown away worthless—in the case of very ordinary household using some ten or twenty cells."

Indeed, if we are to go by the results of the Post Office in this matter, the return from waste materials in batteries for electric lighting would be very small, and probably the plan adopted of throwing them away as worthless would be adopted. The German Imperial Telegraph Department acts on a different system, and the waste material is carefully more favourable terms, for according to figures recently published by us (see Electrician, vol. xxxv., page 606) the department recovered no less than 2½ per cent. of the total materials consumed in their batteries. During the year 1881-2 Mr. Wunsch tells us that 12,300 cwt. of zinc, and 127,105 cells in use in Germany, and 27277, or about 22 per cent., was recovered by the sale of battery residues consisting of lead, copper, and zinc salts. As compared with this insignificant sum realised by our own Post Office, the difference is very striking. The normal cell in the German telegraph service is also a form of Daniell, and we have therefore forced to conclude that it is by no merely saving up, instead of throwing away, the zinc solutions and other materials, as well as the copper "mud," and disposing of them in a proper market, that the striking difference exists. English chemists are within their rights when as well as the German ones, if the matter were brought before them. It will then be seen that Mr. Probert has been unfortunate in his example of the return to be expected from waste products. Moreover he has apparently overlooked two very important factors in the problem. He has overlooked the fact that electric light batteries, working at a high pressure so to speak, and supplying powerful currents, consume much more materials than telegraph batteries, working comparatively feeble currents through a high external resistance, and working intermittently. His own figures may be brought forward to show how much the waste of materials in a lighting battery is. Suppose for example that 25 per cent. of the 700l. 10s. expended in his battery for 100 lights were obtained for waste products, the sum would be 167l., which is almost the exact figure realised by the "black mass" of the whole 30,000 cells of the Post Office. And this estimate of 22 per cent. is not too high for other batteries than Daniells, which are also very properly utilized. For some electric light batteries now in the field it is much too low. We are acquainted with one which, in a chemist's hands, returns much more than 50 per cent. of the original cost of the zinc alone. This brings us to the other matter overlooked by Mr. Probert, namely the utilization of the depolarizing solution, as well as the oxidant solution, and also the gases liberated. For example, in the Holmes-Barke battery, the nitrous gas can be utilised by forming nitrate of ammonia solution with it. Indeed, the whole matter is in its early stages, and there is ample room for enterprise in the chemical utilization of waste battery products. When the matter has been properly studied, as it will be, if batteries are used for lighting, it is very possible that a considerable percentage of the cost of materials will be returned from the utilisation of the waste materials. At one time the residuals from gas manufacture presented a more hopeless problem.

Recent Improvements in Voltaic Batteries.

It is evident that the advent of the dynamo-electric machine and its wonderful progress as a generator of current have not unfairly arrested the attention of scientists and inventors from other and older methods of producing current. For a time the dynamo-electric machine seemed to be encroaching largely on the broad territory covered by the voltaic battery, and to many it seemed that it would eventually replace the latter in nearly every case. But there seems to have been a kind of reaction, and now the field of the voltaic battery is wider than ever, and its success most promising. Not only does it hold its own in every application where it has long since been useful, but it even promises to fill a new want. Between the dynamo-electric machine and the voltaic battery a gap exists which recent improvements in the latter are striving to fill.

Thus the voltaic battery is now being used quite extensively in operating small motors. Its use for electric lighting on a very small scale has been but a matter of experiment thus far, but those who are apt to speak of it as something that will soon be forthcoming. The result is that more interest is felt to-day than ever in the study of the voltaic battery, and the improvements are multiplying in a manner that promises to effect a solution of the problem.

We have been anxious to contribute to this important development by supplying readers of THE ELECTRICAL WORLD with every new detail of information bearing on the subject. The many letters which we receive from various parts of the country show that in doing this we are providing useful intelligence. We can say, for this very pleasure, therefore, in giving extended space to some recent experiments with voltaic batteries, which we hope will be interesting to all our readers.

A new form of single liquid battery, possessing several features of merit, has been recently patented in France by MM. de Lalande and Chaperon. The elements of the battery are copper and zinc, and the exciting liquid is composed of water, containing 30 to 40 per cent. of caustic potash. With such a combination there is necessarily a tendency to the evolution of hydrogen at the copper plate in consequence of the decomposition of the water that furnishes oxygen to the zinc plate. To obviate the consequence of the presence of hydrogen on the copper plate is polarization, and thus the available electromotive force is reduced. In the battery under notice, this difficulty is provided against by a depolarizing mixture of manganese dioxide and pulverized carbon. The manganese liberates the oxygen which combines with the hydrogen evolved at the negative plate. MM. de Lalande and Chaperon have also provided a depolarizing agent, namely, oxide of copper, which is placed near the copper plate, and furnishes oxygen to the hydrogen evolved, by electrolytic action.

Fig. 1 shows a simple form of this battery which results somewhat the gravity cell. At the bottom of the glass jar F is placed a thick cake of the depolarizing mixture of copper D. An insulated wire C connected with this cell constitutes the positive pole of the battery. The battery element consists of a large rod of zinc oxided into a spiral form B and suspended to the cover E and provided with a binding post F. A rubber tube G covers the zinc, the action of the zinc so as to prevent its being worn off at the level of the surface of the liquid. A rubber tube like the ordinary "crowfoot" zinc used so extensively in this country would answer equally well, the upper portion being suitably insulated by rubber cement or other means.

To avoid the inconvenience of handling the potash the quantity of the substance in the solid state necessary for each cell is placed in the steel iron vessel used to hold the oxide of copper and the vessel closed by a cover kept in place by an India rubber band. It is necessary to set up the battery then is to open the vessel containing the potash and to place in the bottom of the glass jar. The vessel is then filled with water and the oxide of copper in the form of a powder is thrown in and settles in the vessel. The inventors have included a Leclanché "prime" battery for forming prime of their depolarizing oxide in certain ways. The best method of doing this is to mix the oxide of copper with some oxychloride of magnesia in the form of paste, so as to form a thick cream that is then placed in metallic oxide, where it "sets" in a short time, specially made thin hollow cones of zinc, which are held by India rubber bands. The positive binding post C is attached to the cover. This is the same as used in the Leclanché battery and passes through the centre of the cover, it being kept from contact by a rubber tube D, the joints being made air-tight. The cover is also provided with another rubber tube H, which is split, and forms a kind of valve. The vessel may be hermetically closed by means of a piece of India rubber placed over the neck and cover as at H. This potash used for the solution is either used in the glass jar or in separate short-iron box. The writings also contemplate a cell having only one prime, but this occupies a very small space. The use of vessels is a great item or copper, which remains unaffected

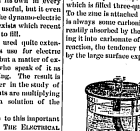

FIG. 1.

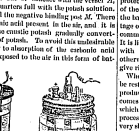

FIG. 2.

tory is prevented by pouring a thin layer of heavy petroleum oil, which has previously been boiled with caustic potash, on the surface of the solution.

The electromotive force of the batteries of MM. de Lalande and Chaperon is of the usual order, but as the internal resistance is extremely low. With plates ten centimetres square, the resistance would not be above ½ of 1 ohm. The volume of current which they produce is consequently very great. Other types can give the same results in short circuit, and the large type can give easily from 15 to 20 amperes. Two of these cells give more current than one large size Bunsen cell.

These cells give a remarkably constant constant. The inventors state that after 24 hours' continuous work, despite the surface of zinc acted upon, the battery can work without appreciable polarization, and it is almost completely exhausted. The reactions which take place in the solution as it becomes charged with zinc do not change the internal resistance materially. The solution is not acted on, and it is done principally to the gradual reduction of the oxide of copper to the metallic state. The solution has no effect on copper oxide, but by its reduction and transformation into metallic copper its resistance increases. It follows that the copper oxide battery can give a current of considerable volume in a circuit of low resistance while, as is well known, the Leclanché battery would become polarized rapidly under the same circumstances. The battery is entirely free from all local action, however, the solution has no effect whatever of itself on amalgamated zinc and copper. The zinc is therefore consumed and the oxide decolorized only while the battery is in use.

The energy contained in the oxide of copper and potash

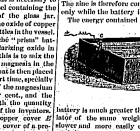

FIG. 3.

battery is much greater than that "stored" in an accumulator of the same weight, while the delivery is much greater than that of the Leclanché battery. The potash used in solutions concentrated to 20, 40 or 60 per cent. will not dissolve the oxide of zinc formed, the zinc resulting from a quantity of zinc of over one-third its own weight. The quantity of copper oxide to be used is about one-fourth higher than the weight of zinc consumed in the reactions. These data enable the necessary constituents of the battery to be condensed into a relatively small space.

The oxide of copper batteries have given interesting results, as regards the telephone. Indeed, the fact that it is exempt from polarization, while it presents all the merits of the Leclanché battery, would suggest it as specially to repositions theoretical performances as a distance, it is necessary to provide five or five separate batteries of Leclanché cells, in order that the one in use may be re-

placed by another the instant it becomes polarized. A single series of the oxide of copper elements will suffice in such a case, because it is free from polarization. The inventors state that three cells were used each day for working some fifteen carbon button transmitters for more than three months without materially weakening. The cells can be worked for hundreds of hours on low resistance circuits, and this efficiency can be obtained from them at any desired moment, for example, many months after they have been set up. The only precaution necessary in order to maintain them in this state is to add enough potash to protect the solution from the access of the carbonic acid of the air by a current of caustic soda may also be used for the battery instead of caustic potash. It has the advantage of being much cheaper, being readily obtained in commercial form and not being of a deliquescent type. It is likely, however, that the electromotive forces obtained with this substance is a little lower, and the potash is otherwise much to be preferred, because it is less apt to give rise to the "climbing salts" which are so disagreeable.

When the oxide of copper battery is exhausted, it may be restored without difficulty. The copper oxide used is a product of all establishments where copper is worked. It comes off the surface of the copper in the form of scales, which have to be reduced again to the metallic state by a process of annealing. The expense of the oxide may be very slight in those regions where it is to be had. But the saturated oxide of the cell may be used for metallized gilding easily. It will become spontaneously oxidized on exposure to damp air, or else it may be heated in an oxidizing flame. Another method is to charge the exhausted cell as if it were an "empty" accumulator, by which operation the positive conditions of the cell are restored to their primitive condition. The copper now appropriates all the oxygen, while the oxide of zinc is reduced to zinc by oxygen, and becomes metallic in the form of a spongy deposit. The zinc is not sufficiently coherent in such a case, and would need to be reset, unless it were deposited on a well amalgamated zinc plate, the mercury of which would cause it to adhere to the zinc surface.

The battery presents interesting qualities, as a whole, and we should not be surprised to find it soon replacing the Leclanché and the gravity cell in many instances.

Some experiments with one of the cells of MM. de Lalande and Chaperon have just been made at the laboratory of the Industrial School of Physics and Chemistry at Paris, by M. E. Hospitalier. The results obtained are without doubt of interest. The practical results of this battery and we reproduce M. Hospitalier's report from *L'Electricien* as being of great interest in this connection.

"The weight of the element was thus distributed:

	Grammes.
Glass jar	454
Zinc, brass box and conductor	1,000
Zinc and slate lid	432
Oxide of copper	1,000
Commercial potash — 1 portion as at per cent.	300
Total	1,764

"The battery, the initial electromotive force of which, one hour after being set up, was 0.78 volt, was left in circuit for six whole days through a resistance of German silver wire of 8.8 ohms. The difference of potential at the terminals of this resistance was by means of a Thomson reflector Sir W. Thomson. Thus the external resistance R, and the difference of potential E, at the terminals of this resistance being known, it is deduced from them the intensity of current, the quantity of electricity supplied, and the corresponding chemical energy.

"The current supplied was, on an average, half an ampere during six days, or 261,936 coulombs. The total quantity of electricity supplied was 252,000 coulombs, the weight of zinc consumed 98 grammes, which corresponds to a theoretical polarization of 260,000 coulombs. This is a most important point, and very favorable to de Lalande and Chaperon's battery, for it shows that the local action is practically nil. The energy that the battery is capable of supplying is therefore available at will, without it being necessary to disturb the elements in order to withdraw the zinc from the liquid, as in the bichromate of potash batteries, for example. The useful, available rendering is 0.67 kilogrammetres per second. In six days, therefore, the battery could raise 11,008 kilogrammetres of available electrical energy. This exceeds the results obtained up to the present with accumulators of the same weight, but we must add that the supply is much slower than with these latter. It is however easy to increase this rendering by increasing the surface of the element and by diminishing the distance of the oxide from the zinc plate. The result then increases more rapidly than the weight, and tends to approach that of the accumulators.

"The remarkable constancy of the rendering must be attributed chiefly to the fact that the product of the reduction is metallic copper, which is a good conductor, and that the solution of an alkaline salt of zinc which as formed presents a conductivity almost equal to that of the solution of potash. For a given weight of zinc dissolved, about three times the quantity of solid potash is required, and a quantity of oxide of copper, equal to 1.25 times the weight of the zinc. In our experiment the consumption of zinc being only 98 grammes, required in the reaction only 250 grammes of solid potash and 112 grammes of oxide of copper, i. e., the battery was exhausted at about two-thirds of its capacity."

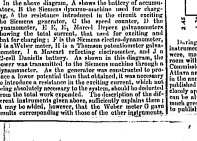
THE FAURE ACCUMULATING BATTERY.

A series of highly-interesting experiments has lately taken place at the Conservatoire des Arts et Metiers in Paris with the Faure accumulating battery. These experiments, made under the exclusive direction of a committee so eminent as that who carried out the experiments with the Planté battery, and of which the Abbé Moigno was subsequently the Paris Electrical Exhibition, as chairman of the Conservatoire, have been of a kind to leave no doubt as to the conclusions, leave little to be desired to make their conclusions. We append a translation of some remarks on the trials furnished us by the *Société Forez et Lumière*. They extended over five days, during which time all the special features of these accumulators were examined, such as the construction of stored electric energy and the quantity and actual efficiency of the same, the loss of energy, and results generally, so that these characteristics appear sufficiently to those described by Sir William Thomson some months ago. The members of the Commission were M. Tresca, President, and MM. Polier, Jaubert, and Alfred, with the assistance of M. G. Trasenx. M. Gérard watched the experiments on behalf of M. Bolgiato.

The accumulators tested, in all, were of 46 cells, were of the laboratory type; they had a theoretical value of 0.94 in. in the laboratory type; they had a theoretical value of 0.94 in. in the laboratory type; they had a theoretical value of 0.94 in. with the combined value. The electrical resistance of this type is high, and this caused a rise of potential in charging and discharging, somewhat greater than is the case with the industrial type, such as would be employed for tramways when the period between charging and discharging would be necessarily short. It is important to note the cause of this difference, as it is due to the fact that the former others are spiral at bottom. It is well known that the accumulator consists of two formation plates, on which are applied the materials which by the subsequent process of "formation" become the active agents in the battery, such as oxide of lead, spongy lead, &c. The Planté battery is rendered active by the disintegration of the plates themselves. M. Faure, while retaining the surface of his formation plates, adds materials to great extent, and thus increases the capacity of the battery, but save on the absolute storage capacity, which depends only on the thickness of the spongy lead applied to the plates, and as these points affect largely the cost of production, he made batteries either of high or low resistance for different purposes. The Planté accumulators used at the Conservatoire were formed of two plates rolled spirally. The positive plate was 28 m. in thickness, and the negative 1 m. The former was 22 m. thick; the negative plate was 28 m.; both were perforated with holes 2½ m. in diameter, and they were covered with a paste of minium in the proportion of 100 lb. per square foot of plate. Annexed is a diagram showing the connections of the apparatus used in these experiments, which were commenced on Wednesday the 23rd inst. However, before the actual experiments were made, resistance coils for testing the batteries' internal resistance were carefully constructed. This is the case for the secondary, and lasted over six hours, during which was noted towards the end, the fall of the potential with an average current, in working as a unit the potential of the two end terminals of the 35 elements in series, and the voltage also the luminous intensity produced. This preliminary experiment was necessary, though it had nothing to do with the question of the storage capacity of the battery, or rather the efficiency between practical limits during which the lamps would give a uniform and satisfactory light. These measurements marked the limit of the experiment, which, moreover, was fixed as in its conclusion by the rapid falling off of the luminous intensity.



In the above diagram, A shows the battery of accumulators, B the Siemens dynamo-machine used for charging, C the resistance coils, D the Siemens dynamo, E the Siemens dynamometer, F the speed counter, H the dynamometer, G G, E, Marcel Deprez galvanometers showing the total current, that used for exciting and that for charging; F is the Siemens electro-dynamometer, G is a Weber meter, H is a Thomson potentiometer galvanometer, I a Marcel reflecting electrometer, and J a 62-cell Daniells battery. As shown in the diagram, a power was transmitted to the Siemens machine through a counter-shaft, and the intermediate gear enabled to produce a lower potential than that obtained, it was necessary to introduce a resistance in the exciting current, which, although absolutely necessary to the system, should be deducted from the total work expended. The description of the different instruments given above, sufficiently explains them; it may be added, however, that the Weber meter G gave results corresponding with those of the other instruments.

The electromotive force of an accumulator was found to be 2.15 volts, and in reading the figures of the potential column obtained on the Thomson potentiometer, it must be remembered that the deflections obtained by this instrument are proportional to the tangents of the deflection and not directly proportional to the sines of the angles. Some small correction will be needed in the figures of the Table given below, but as they require delay to check, and as the work will be published by the Commission with all detail, it is preferable to give them, though not absolutely exact; they show the average results as nearly as time permitted them to be obtained:

No. of Hours.	Total Foot-Pounds.	Foot-Pounds per Square Foot.	Total Current Ampères-Hours.	Average Current.	Potential Used.	Days.
5.30	17,505,800	44,091	95	17.15	35	Wednesday.
7.30	22,780,200	57,351	126	17.15	30	Thursday.
7.30	22,780,200	46,031	99	7.89	32	Friday.
2.45	6,175,900	46,031	17.5	6.48	32	Saturday.
23.45	68,241,600	49,559	193.5	8.5	31.75	Mean.

The resistance mentioned above as having been introduced into the exciting circuit of the generator, on account of the low resistance of the electrics, was measured, and it was calculated that 6216 foot-pounds per minute represented the mean of the work thus uselessly expended, so that the average useful work per minute was 43,343 foot-pounds. The mean potential reading of 31.75 corresponds to 27 volts for the battery of 35 elements, and the charging equal to a mean effective electrical energy of 10,701 foot-pounds per minute, or 0.247 horse-power. The 27 volts, however, expended, and consequently a duty of 74 per cent.; this might evidently have been higher, and is partly explained by the great speed given to the machine—1050 revolutions—and the low duty demanded of it.

The operation of discharging the batteries was performed at twice with an interval of thirty-six hours between the two processes. It was commenced at 11 A.M. on Tuesday January 1, and was continued until 10 P.M., the same evening, when the potential descended at 10 o'clock the following Tuesday morning and was finished at 2 P.M., though it virtually concluded at 1.30 P.M., judging from the luminous indications. During the operation of discharge the desire to approach practical conditions as far as possible, and to obtain a uniformity in the power given off, led to some slight approval conditions, which, while perhaps not absolutely correct in principle, were sufficiently practical considerably the practical results. At first the discharge was made with thirty cells, the five others being successively added with the intention of increasing the uniformity; these additions were made by the manipulation of a commutator. The second stage of discharge was effected similarly, commencing with thirty cells, and then rising to thirty-two and thirty-five. The following curve will be easily calculation with regard to how were the curve of discharge if the three [illegible] five cells had been used at once; this curve is shown in dotted lines in the annexed diagram.

During the period of discharge the arrangement of instruments resembled that used for charging. There were, moreover, eleven Meslin lamps placed in a dark room with the photometer placed at the disposal of the Commission; the measurements were made by MM. Allard and Leblanc. We must point out that the figures in the annexed Table are not absolutely correct; they are the average results of the tests made, and they will be sufficiently approximate averages of the absolute results that can be always obtained. The number of readings was much greater than the space at our disposal will allow us to publish.

Result of Discharges a Faure Battery of 35 Cells with 11 Maxim Lamps.

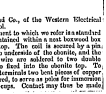
A STANDARD OHM.

IN the engraving below we illustrate what, in the electrical apparatus, may justly be considered a novelty, recently designed by Messrs. King,



Hendilson, and Co., of the Western Electrical Works, Ireland.

The instrument in which we refer is a standard ohm coil, contained within a neat boxwood box with ebonite top. The coil is secured by a pin, and rest to the underside of the ebonite, and the ends of the wire are soldered to two double terminals, also fixed into the ebonite top. To both of these terminals two best pieces of copper rod are soldered, to serve as poles for immersion into mercury cups. Contact may thus be made through the mercury cups, or by placing the terminals under the terminal screws. Each coil connecting wire under the terminal at the Current-in compared with a standard issued at the Current-ish Laboratory, and a certificate guarantee given that its resistance is correct to within one-hundredth part of an ohm as defined by the International Congress.

To science teachers and others engaged in experimental electrical work such an instrument as that described is invaluable, as affording means of testing resistance of conductors, batteries, &c., or of measuring resistance coils with a correctness hitherto unobtainable, except by means of standards out of the reach of many on account of their high price.

THE PENRHADD ACCUMULATOR.—Messrs. A. R. Sennett and Co., of St. Buttolph-street, London, are the manufacturers of the Penrhadd electrical accumulator, which has been in use for some time in various electric installations. They have modified it for use as a private lamp, and have combined it with a magnetic switch. This switch must be operated by a powerful electro-magnet to alter the connections for charging, and, therefore, is proof against all attempts on the part of the misers themselves.

We illustrate above a new form of movable and self-emptying street mud-bin which has recently been introduced by Mr. William Heath, of No. 17, Tintern-street, Brixton, and Whitehall-place. The arrangement is very simple, and consists of an iron or steel receptacle which is attached directly to a hydraulic ram, as shown. The ram is worked by the pressure in the water company's main and fills the receiver sufficiently high to command the scavenger's cart. A door in this opened at the side and the contents fall by gravity into the cart, sliding along the sloping bottom of the cage; or if required the latter can be tilted on trunnions. The waste water from the hydraulic cylinder passes into the sump in the pit in which the receiver is placed. The way in which the ram is guided in the base is very simple. A fork on the gaffe is cast on to the interior of the case, and this fits a corresponding notch in the ram, the latter being prevented from rising nearly as large as the case, and so arrives at the same time a stop by coming in contact with the top bar.

Our present method of removing street refuse or domestic garbage is offensive and uncleanly, so that any practical improvement by which the operation could be performed should receive every attention.

THE INTERNAL CURRENT IN A VOLTAIC CELL.

*On a Galvanometer for Demonstrating the Internal Current transmitted through the Liquid within a Voltaic Cell.**

By CONRAD W. COOKE, C.E., M. Inst., T.E.

IT is of course well known that when the external circuit of a voltaic cell is closed a current of electricity is transmitted through that circuit, and at the same time a current of equal strength is transmitted through the liquid within the cell. These two currents, it is also known, are not in reality but portions of the same current, and are for convenience known as the external or internal currents respectively, to distinguish that portion of the same current, which flows through the external conductor from that portion which is transmitted from plate to plate within the cell. The former of these is detected by its electro-magnetic and other mechanical effects, producing deflections in galvanometers and electroscopes and results in telephonic intercourse, and it is utilized in all the applications of voltaic electricity.

As far as the author has been able to find out, there has not hitherto been any satisfactory means in the hands of the demonstrator of physics by which the existence of the internal current within a single cell can be made apparent. Certainly, in the course of his early researches, he found that the deflection of a delicately poised magnetic needle by a soft metal rod inserted into the liquid between the plates of one cell of a voltaic battery, so that the needle should lie in a plane perpendicular to those of the plates, and so observed that when the needle was just below the surface of the liquid it was deflected the reverse of that the external current was closed. On lowering the needle deeper into the liquid the amount of this deflection gradually diminished as the depth of immersion was increased, until it reached a position about half the depth of the liquid, when it returned to zero, and after passing this depth it was again deflected, but this time in the opposite direction, its amount of deflection in either case increasing as its distance from the neutral or zero point of no deflection. The cause of this phenomenon, we shall presently see, is the neutralization. If a wire carrying an electric current, when suspended above a free magnetic needle, the latter, obeying Ampère's law, will be deflected with an angular displacement dependent upon the intensity of the current and its distance from the needle; and if the same wire be held below the needle, the latter will be similarly deflected, but in the opposite direction. Since the flow of electricity through the liquid in a voltaic cell is from the zinc plate to the copper plate, the liquid may be looked upon as made up of an infinite number of currents transmitted in a horizontal direction from one plate to the other; and when a magnetic needle is immersed just below the surface of the liquid, all these currents are flowing in one direction, below it, and a corresponding deflection takes place; when, however, it is lowered deeper into the rain, the number of currents above it are equal to the number flowing

SECONDARY BATTERIES.

To the Editor of Engineering.

Sir,—In the report upon the electric light at the "Healtheries," which appeared in your last issue, you refer to the exhibit of Messrs. Parker and Elwell in the following terms:

"The secondary battery is distinguished from the Faure and the Sellon batteries, by being made of cast-iron lead only. The plates are cast in a mould, after which they receive the proper coating, and are then roughly formed by the passage of a current. By this method of manufacture, which was patented in this country independently by Messrs. Parker and Elwell, and by M. Planté, the difficulty arising from the peeling of the oxide is avoided."

As manufacturers of electrical energy are destined to play so important a part in the future, we consider how-ever, that the above is not a correct description of the matter in question, and I therefore venture to ask you to place on record, for the information of those of your readers who may be interested, the subjoined statement, free from any patent specification of September 10, 1881, the other from that of Messrs. Parker and Elwell of August 4, 1882. I would also mention that I called attention to the same matter in connection with M. Gaston Planté's patent of July 11, 1879, in my letter in the *Electrical Review* of September 20, of that year, immediately after the paper by M. Gaston Planté (which appeared in the *Comptes Rendus* of the French Academy of Sciences in August, 1879) was seen by me.

It is not my intention here to enter into questions of patent law, nor into the merits of the various types of secondary batteries upon which I may, if permitted, have more to say hereafter; I simply wish to call attention to the following facts, in respect to the chemical *process or means described and claimed* by M. Gaston Planté and Messrs. Parker and Elwell in their respective patents, that each action by the acids on lead has been a matter of common knowledge since the early days of chemical science, and that their employment in the manner in which any ordinary laboratory lead would adapt it to form a piece of lead to the condition specified by me.

Sellon's, September 10, 1881.

"The plates of the lead may also be employed as one or both sides by means of . . . any chemical process . . . in such a manner that to a suitable depth on each side of the plate a *spongy layer or porous mass or mass or fibres* are produced, whilst the remainder of the thickness of the material between is left *a non-porous, solid core, or homogeneous lay of the surface, whereby the plate is made capable of having formed upon it, and retaining when so formed*, a larger proportion of active material than during the action of the battery than if the plate were employed with its surface in the originally smooth condition."

Parker and Elwell's, August 4, 1882.

"The plates . . . are thereby rendered . . . more readily adapted *to facilitate their development* under the action of the electric current, by placing them in a dilute solution of sulphuric acid or other suitable acid. The plates are then washed, and subjected to the action of a current of electricity, whereby the material becomes in the main converted into peroxide of lead, *a more rapid formation of the plate* if used without such packing."

I am, Sir, your obedient servant,

JOHN S. SELLON.

The Hall, Sydenham, November 24, 1884.

ELECTRIC LIGHTING.

The promised memorandum of the Board of Trade, to serve as a guide in the framing of provisional orders or licenses for electric lighting projects, has appeared, and is an embodiment of the views already expressed by the Board, and to which we referred in our last issue. As the interest of promoters it is to be regretted that this memorandum did not appear six months ago; but it does so the list of orders would have undoubtedly been shorter, and a great deal of labour and delay would have been spared the promoters of the more serious schemes. Probably the Board of Trade did not feel qualified to issue the memorandum till it had acquired the information contained in the classes of the various provisional orders and licenses, and had learned the views held by the advisers of the different local authorities interested. The provisions now issued, refer to six of the principal points that have to be considered in preparing any scheme for public lighting, together with some of the auxiliary considerations growing out of the main questions. The first point refers to the area to be scheduled by the undertakers. It is evident that this area should be so selected that it may afford a fair chance to the undertakers both for developing their schemes and realising a profit on their investments, and it is very wisely suggested that while in the commencement a limited area should be allotted to the undertakers, they should have also prospective rights over a second area, to be exercised after a reasonable delay, or else resigned. As regards area, it is presumed that no order that the good faith and financial ability of the undertaking company would be practically demonstrated, that the company should be required within six months from the date of obtaining the order to set apart by special resolution the capital required to carry out the work, or else be immediately deprived at least half the money necessary for works to be executed in specified areas within two years after commencing. In the same way fresh deposits would be required for subsequent extensions, all such sums being approved by the Board of Trade.

As for the source of supply, the memorandum proposes that a system of parallel circuits should be adopted, and that in no case other system should be demanded, either by local authorities or private consumers. It may be mentioned that the whole of the model rules appear to apply specially to incandescent lighting, it being stated "that if it is desired to supply at high tension for arc lighting or other purposes, he may be done under special regulations." Subject to a period of six months immediately after commencing to work, the supply of current must be continuous except where it is otherwise arranged between the undertaker and the authorities. This is very essential obligation, though one that is likely to tell somewhat hardly on the undertakers, and probably cannot always be objected to serious fines for failing to fulfil their part, of the contract. The question of price is to be changed to consumers, and limit of profits, the Board of Trade is reserved, and naturally so, for the first especially is full of difficulties. No satisfactory mode of measuring the quantity of energy used by the consumer at present exists, a charge for a maximum supply would probably be objected to by the public, and a charge for an average consumption would probably result in loss to the company. Time and experience will undoubtedly bring measuring instruments, as well as data on which fair charges can be based, and in the mean time companies and authorities will probably be compelled to accommodate each other. The question of discussing the limitation of profits to the companies is, we think, a little premature.

In order to popularise certain leading ideas, by comparing them one with others, likewise to the public, the Board of Works lay down certain definitions: "The 'working pressure' will be to say, a system under which electricity used by each consumer is drawn off from a double system of mains (in this Order referred to as the positive and negative mains) in connection respectively with the positive and negative poles of the immediate source of supply, by means of service lines forming a series of parallel circuits." The term "standard pressure" is defined by the following sentence: "The potential at corresponding points of the positive and negative distributing mains shall differ at each point by a constant difference (in this order termed "the standard pressure.)" This standard pressure is to be allowed to range between the limits of 30 volts and 200 volts for continuous currents, and 60 volts and 100 volts for alternating currents. Probably the lowest limit contemplates the introduction of an incandescence lamp not yet in the market, adapted for a very low electromotive force, with regard to the higher limit, although it is a reasonable maximum for currents flowing through wires within houses or otherwise exposed, it appears liable to hamper supply companies as regards the utilisation of their main conductors. It is also probably with an idea of some alternating current machine not yet in signal, that it is provided that "the number of alternations per minute of alternating current shall not during the hours of supply be less than 600, or such other number as may from time to time to be fixed by the undertaker and sanctioned by the local authority." Although this sentence begins a very elastic interpretation, this seems to be that the speed of alternations shall be at least such as to secure a continuous and not an intermittent light, which would be produced if the number of extinctions and re-illuminations, in the case of an arc lamp, were not sufficient to maintain the effect of a permanent light to the eye.

The following is a brief synopsis of the Board of Trade propositions for regulating the condition of supply to a consumer. The undertaker shall be compelled on demand to furnish a current to any premises situated within 25 yards of the conductor, by the proprietor or occupier of such premises paying the cost of all service wires on his premises, and for any distance beyond 30 ft. from the mains. The would-be consumer must state to the undertaker the maximum current he requires, and must contract for a period of two years to receive the supply, giving security for payment if required, and binding himself to pay for the supply at least 20 per cent. per annum of the charge incurred by the company in laying lines, &c., for furnishing him with the current. The undertakers shall be bound to furnish a current "not exceeding what may be reasonably anticipated as the maximum consumption on his premises," and they have also an option of a limitation, by the increase or diminish such maximum, upon the consumer paying the expenses attendant on the alteration. It is of course absolutely necessary that the undertakers should have every possible protection afforded to them, but the necessity of entering upon a costly experiment for a period of two years, combined also with the giving security for charges to be incurred, will double many, otherwise attractive schemes, and will be a serious disadvantage.

The prices to be charged by the undertakers to the consumer—unless special agreements are made—shall be based either on the quantity of energy contained in such supply, or the actual quantity of electricity supplied, or the number of hours during which the supply is used, and the maximum current with which the consumer has agreed to be supplied. Either of these modes is attended by many difficulties; the last-named appears the simplest, though probably not the least complicated to the consumer, who would nevertheless be under the disadvantage of paying for the full amount of current though he might have only one light burning. This point leads to the Board of Trade remarks upon meters, which are wisely confined to generalities, as the "certified meter" which is to receive official approval has not probably been constructed. Such a meter is to register the energy contained in any supply of electricity to a consumer, or the quantity of electricity supplied, or the number of hours for those amounts being defined as the "value of supply."

The regulations as to safety appliances appear to be well considered and complete so far as present experience goes. They refer to the proper insulation and enclosure of conductors, to limit of temperature allowed to flow through a given section of wire; the means of testing all the current mains (in this Order referred to as the positive and negative mains) in connection respectively with the positive and negative poles of the immediate source of supply, by means of service lines forming a series of parallel circuits." The term "standard pressure" is defined by the following sentence: "The potential at corresponding points of the positive and negative distributing mains shall differ at each point by a constant difference (in this order termed "the standard pressure.)" This standard pressure is to be allowed to range between the limits of 30 volts and 200 volts for continuous currents, and 60 volts and 100 volts for alternating currents. Probably the lowest limit contemplates the introduction of an incandescence lamp not yet in the market, adapted for a very low electromotive force, with regard to the higher limit, although it is a reasonable maximum for currents flowing through wires within houses or otherwise exposed, it appears liable to hamper supply companies as regards the utilisation of their main conductors. It is also probably with an idea of some alternating current machine not yet in signal, that it is provided that "the number of alternations per minute of alternating currents

A PORTABLE MINING STORAGE BATTERY.

At a recent meeting of the Engineers' Club of Philadelphia, Mr. C. Henry Haseltine exhibited a portable storage battery for mining and exploring purposes, with small incandescent lamps. The battery was a modification of Plante's, devised by Dr. E. T. Starr, of Philadelphia, the electrodes consisting of W-shaped plates of sheet lead arranged over each other, the convexity downward, with a slight interval between them, their ends being attached to a lead frame by burned joints, the interstices between the plates being filled with finely divided metallic lead, exposing a large surface to exhalation and reduction when subjected to dynamic electric or voltaic energy, and, in turn, giving off a large percentage of the stored energy in incandescent lamps placed in the circuit. The battery is 9½ inches long, 2½ inches high, and 5 inch thick, and is said to maintain a small two-candle incandescent lamp at incandescence for about one hour. A battery sufficiently large to use an eight-candle lamp for ten or twelve hours would, consequently, not be too large or heavy to carry conveniently for mine or other underground exploration.

Scien. - June 24, 1882

ELECTRICAL STORAGE.—On January 13, Mr. J. W. Swan delivered a lecture on "Electrical Storage," in the hall of the Literary and Philosophical Society, Newcastle. The lecturer alluded to the large amount of public interest taken in the question of electrical storage, or, as it is also and generally termed, "the storage of electricity." He stated that to produce any of the practical effects now demanded of electricity, such as lighting of houses or driving machinery was beyond the power of electricity stored in any manner, and that the term, storage of electricity," was a misnomer. What was meant was the storage of energy by means of electricity, and in such a form as to be immediately capable of reproducing electricity. Coming to the question, In what form could they store energy to be available for the production of electrical effects? they found that there were only two forms in which energy could be so stored as to be dormant, and not liable to leak out or waste. The one form was as mechanical energy, and the other as chemical energy. The lecturer then proceeded to explain the various forms of storage, illustrating his remarks by an exhibition of various kinds of cells used commercially for lighting by means of stored electrical energy which he had in some of them. Amongst the cells shown were those of Daniell, Plante, and M. Faure. After explaining the chief characteristics of these cells, the lecturer proceeded to refer to the paper on "A New Electrical Storage Battery," communicated by Henry Sutton, of Balham, Victoria, to the Royal Society. This paper, he said, described various experiments in electrical storage, and in its remarks on the exhibition of various kinds of cells used commercially for lighting by means of stored electrical energy which he had in some of them. Amongst the cells shown were those of Daniell, Plante, and M. Faure. After explaining the chief characteristics of these cells, the lecturer proceeded to refer to the paper on "A New Electrical Storage Battery," communicated by Henry Sutton, of Balham, Victoria, to the Royal Society. This paper, he said, described various experiments in electrical storage, and spoke of the great effectiveness of an arrangement which was a sort of a cross between Daniell's and Plante's cells. Mr. Sutton stated that in process of working the cell at the last readily enabled to a great depth, the peroxide forming a regular layer on the surface. From experiments which Mr. Sutton had made he could fully confirm Mr. Sutton's statement as the facility with which a thick coat of peroxide formed on the intricacies lead in his cell, giving it large capacity of storage. The discovery of this means of rapidly forming a thick coating of peroxide was incredible. While experimenting with Sutton's cell the lecturer found a much greater tendency to the formation of the deposit of lead sponge, connecting link between the peroxide and the lead plates, which quite destroyed its efficiency. It therefore occurred to him to discard the copper solution and the copper plate after the coating of peroxide had been formed on the lead, and to use the oxidized contact lead plates alone with diluted sulphuric acid. He therefore connected the oxidized plates in this manner, and he was glad to say he had obtained the most excellent results with the cell thus modified. The storage capacity was large, and the cell worked well in every way. Mr. Swan proceeded to describe and illustrate the results he had obtained with Sutton's cell, and also with the modification he had described. The hall was lighted up from thirty cells which lethal brought ready charged. A portable case containing cells and having a lamp connected with it, such as could be easily carried into a coal mine, was also shown, the light being very much superior to that of the ordinary safety lamp. The lighting of railway carriages by the same agency and of electrical storage was discussed, and the lecturer also alluded to the probability of electricity being applied to the production of motive power. At the conclusion a vote of thanks was accorded to Mr. Swan.

PRIMARY BATTERIES FOR ELECTRIC LIGHTING.

[2203].—A short time ago, the writer was able to obtain, through your valuable paper, some useful information, and determined from that time to become sandcricket.

He has now, after a short every hour, inquiries of primary batteries for electric lighting, some of them exceedingly absurd; others evidently practicians who had bought so-called electric light batteries, and had found them unsuitable, useless, and practical. Information how to work them, but probably - even comparative after-success.

Electric lighting by means of primary batteries is not such a myth as some of your readers may imagine. It can be done with perfect success; but you must go beyond quart jars and the apparatus usually sold for experimental work. The battery must also be constructed and made to charge automatically with arrangements for charging and discharging by simple mechanical means, thus protecting the electrical connecting and disconnecting of terminals, and the necessary liability to bad contact, and probably unestimated introduced resistance, and the waste and tear of same. Again, the proper proportions of quantities of lesser and outer cell solutions must be maintained, and the cells must be coupled up to give the results which are most economical, and which may vary with the type and number of lamps required. The best, of course, have the smallest possible internal resistance. Another liability to detach by coatings, that cause low by quantities, but became detached in large flakes; that short circuited the cells, and thus stopped the light. Short circuiting of cells, the circulation of fluid being impossible, the action of local currents on the zinc plates, and consequent waste of same, and thus every sort of irregularity began. Now regularity or uniformity is of the most vital importance, more importance in any form of battery. If any part of the battery is stronger than the rest, every cell or plate in a cell is pushed to better energy and if any cells of a battery are better than the rest, the finished better away. Regularity

tain other persons whose heads were often carelessly exposed to the sun's glare without any adequate covering. The need of care which these ailment has since much increased. Field-workers and holiday-makers have multiplied ten-fold, and with one and all the weather, and how to meet it, is the first consideration. The fact is that sunstroke is natural. Thus, while we trace the continuity of causes, we first look after direct exposure to the solar rays, we next consider the fact that more concealed heat, intensified and aided by confinement in small or imperfectly ventilated spaces, is equally efficient to the same end. Various circumstances predispose to latent heat. Prominent among these is the nervous and generally sensitive habit of many stimulants to quench thirst. The object of drink is to satisfy water. The natural object of diet in the summer is therefore simply to make good this loss with as little stimulation of tissue as may be. Such stimulation tends to raise temperature by needlessly provoking chemical change, and is therefore mentally prejudicial. He who would enjoy fresh air and sound sleep must live very much on vegetable food, and drink as lightly as possible. Over-stimulating alcohol, by, and actually, at bed-time, is the very bane of the rock, in particular, proves to be suitably covered. Many inconvenience exist for this purpose. The tropical custom of wearing a damp handkerchief within the hat is occasionally useful. Puggaree should be light-coloured, such as linen or thrum, to allow of free respiratory movements. All such impediments to the healthful circulation, provides a condition favourable to heat-stroke. For the same reason excessive exercise or work is dangerous, through the exhaustion which follows it. Allusions in these columns to this have lately been adopted for the employés on the Metropolitan Railway. It would be well if such a precaution, which in fact were minimised, as far as practicable by other companies, and on the Government services. Associated with preventive measures, cold bathing in moderation must not be forgotten; for prevention, there is even more valuable than the free exposure of actual electricity, for which it forms a chief therapeutic agent. The latter, however, must not be taken into the body should not be overlooked by prolonged exercise or other cause.—*Lancet.*

FORMATION OF COLOURING MATTERS BY ELECTROLYSIS.

As long ago as 1875 M. Goppelsroeder announced to the Industrial Society of Mulhouse that, while studying the action of the galvanic current upon organic bodies (and principally those of the aromatic series), he had observed a large number of interesting results, among which were those that demonstrated the fact that, through the electrolysis of benzol, colouring matters were formed at the positive or negative pole. He was precluded that by the use of a cheap generator of electricity colouring matters might be cheaply manufactured by means of different bodies of the aromatic series. Gerard and Lairo have undertaken a process by means of which aniline blue is prepared without the use (as usually) of chlorine of vitriolline. In this process the product employed is diphenylamine, which is prepared by the reaction of aniline upon its hydrochloride, and which, to convert diphenylamine into blue, it is mixed with concentrated sulphuric acid, and kept at a temperature of from 100° to 120° for three or four hours. To this but this reason, a similar but cheaper result is the same blue is obtained by a simpler and cheaper method that is through the electrolysis of a solution of diphenylamine. The blue is then obtained at the positive pole. In order to produce the current he employs either a bi-acetic bichromate of potash, or a multi-cellular pile on a Bunsen one. To prevent as much as possible the diphenylamine from upon the effect of the other, he employs porous clay cylinders (such as are used in the Bunsen pile) filled with the part of the liquid which is not to furnish the principal electrolytic product, and into which is immersed the secondary electrode (Fig. 1); or else he divides the electrolytic liquid between two vessels, and connects the two currents one with the other by means of forcible inverting-paper, its use employs, as a constructing cell, a glass cell of cotton wicks (Fig. 2) covered with parchment paper from the surface of the liquid, so as to prevent the drying up of the conducting fluid. In the same way, he has used asbestos paper or cardboard, instead of parchment. Fig. 3 shows a cell with two electrolytic fluid, &c. If necessary, he increases the conductibility of the liquids by the addition of a little sulphuric or hydrochloric acid. The conducting fibres become more less evident, as one pole by weight of benzene will in about 20 parts by weight of water, or filled with some alkaline liquid. In this latter compound the benzol element, separated from the other two by a porous partition, is filled with a solution of potassic bichromate, containing concentrated sulphuric acid of from 1·3 to 1·4 specific gravity. The object of the inventors was to find an improved constant cell, and they claim that the results which they have obtained by the above patent it may be assumed that the results they have obtained by the above factory as they describe.

Several devices have been patented in which peroxide of lead is employed in secondary voltaic cells, one of the most promising being probably that of Messrs. Sellon, Volckmar, and H. Jones. In that the negative element consists of lead or carbon in contact with peroxide of lead, each portable being preferably obtained by the electrolysis of a solution of oxide of lead, or by the conversion of spongy lead into peroxide. When carbon is employed as the negative element, it is very advantageously to in the form of small fragments of coke, or of graphite, or of any one material, or other variation of the carbon fragments being filled with lead peroxide. Sulphuric acid is used the lead peroxide may be mixed with a solution of chromic acid obtained electrolytically. As the positive element, the inventors employ lead in a highly porous condition, as obtained by a granular or rare degree of compression of the metal reduced from its oxides or salts by chemical decomposition or by electrolysis. In this case a precaution of lead is a state of minute subdivision produced by mechanical means. As the electrolyte they use dilute sulphuric acid, preferably imbibing in addition a small proportion of sulphate or tartrate of ammonia.

In constructing a voltaic the three metal, iron, zinc, and peroxide, separated by the intervention of cells of porous material, it is they have covered with a thin layer of cotton wool, or other fibrous material. Thus, Mr. F. H. Vowles patented a battery composed of elements such as iron and zinc for a material in solution of caustic soda or potash. One of the patents of the present year is that obtained by Messrs. J. S. Spence and J. E. Chester, which we have previously noticed under the head of "Domestic Primary Battery," p. 108, as the cell which is to give current for striking, &c., copper-zinc battery, in which a solution of caustic alkali is used as the exciting liquid, and the depolarising substance consisting the copper in oxide of copper, the inventors find that if the spent or partially spent solution be withdrawn from the cells the zinc therein contained can be obtained as the oxide of zinc of commercial purity, by passing into the zinc solution carbonic acid, which throws down the zinc as the white carbonate. The resulting carbonate of the alkali is then boiled with fresh portions of zinc, when collected, washed, dried, and ignited, gives off carbonic acid (which can be used again in another portion of the spent liquid), and leaves behind the pure oxide of zinc. The caustic alkali obtained by this process may be evaporated to dryness, and of alkaline carbonate obtained in the manufacture form, but it is preferred to boil the alkaline carbonate with caustic lime, so as to convert it into caustic alkali, which when evaporated sufficiently is decanted from the carbonate of lime formed by the double decomposition in the cold, and is used over again for acting upon a fresh quantity of zinc in the galvanic cell.

Another of the patents are those in which the inventors seek to regulate the consumption of the zinc and prevent waste when the cells are not in use by Mr. Courtenay will serve as an example.—The zinc or other positive metal is, as usual, in rods or cylinders, is coated with asbestos paper, the same being previously prepared with a saturated solution of glue in, or other substance which contains, after which the zinc or other metal is carefully coated with one or more layers of the prepared asbestos paper and dried, the object of which is to regulate the consumption of zinc or other metal during the time the metal is in the exciting fluid, by preventing wasting action on the zinc. The negative elements are carbon, preferably platinum or other suitable metal can be used as one cell. The level of the liquid in the porous cells, the inventors preferably use the following strong acid, the middle cell containing water, or water and a small quantity of common salt, or the equivalent of any substance to render the water of greater conductivity in exciting the immobile action of the batteries, the outer cells being charged with compound oxide or any other suitable compound salt. This latter device is becoming very much in favour, protection evidently consider there is an advantage in making cells with three divisions.—Thomas Wood, of Vienna, patents a "voltaic cell," which consists of a vessel of impermeable non-conducting material, divided by porous partitions into three compartments. In one of these compartments is placed the positive element of platinum, carbon, or the like, immersed in nitric acid of 20° to 30° Baumé. In another of the compartments is placed the negative electrode, preferably zinc, immersed in a solution of salt (such as sea salt) of about 15 to 20 of water or in other suitable liquid, which is preferably between the two compartments containing the acid, and contains sulphuric acid of 10° to 20° Baumé.

Amongst recent improvements in secondary batteries we may refer to Mr. A. Rhodin's, in which the battery is built up of a number of alternate lengths of glass, porcelain, vulcanite, or other insulating material, having two partitions of zigzag form, dividing the section of each cell into two compartments, the zigzag branches of the one compartment being interposed with those of the other. In each of these compartments is placed a plate or a number of corresponding zigzag plates, the latter in the one compartment being covered with a coating of peroxide of lead, and in the other compartment with a layer of a compound of lead such as an oxide. The plates of these cells are preferably made very thin, especially their middles being raised a little from the bottom of the trough. Over the sheets is poured the exciting liquid of sufficient depth to cover the partitions, and sometimes, one sheet, each such sheet, form the electrodes of the cell.' Instead of using sheets of lead or copper, the inventor may use wire or the two compartments may be separated by a perforated zinc plate, which is covered with a layer

one-fifth, so that with a scale derived from equal quantities of heat, when an air thermometer showed 200°, chlorine would give only 155°.

As a result, if we imagine two air thermometers graduated—one, as usual, by equal increments of expansion, and the other by equal additions of heat (which would be the same thing if the specific heat were constant), the two would agree at 0° = 200°, and would gradually differ so that when the first = 4,500°, the other would show 8,816° as the number of units of heat required to produce the expansion. M. Berthelot contends that this result shows that the actual grouping of the atoms of gases is much more complex at the ordinary temperatures than the ordinary chemical formulæ recognise, and that the effect of increased heat is to resolve these groupings into more simple forms.

This subject, once thus opened, must needs be thoroughly examined. It may be suggested as possible that just as dissociation takes place in compound gases, as, for instance, ammonium chloride, which slowly doubles its volume, or, as in ozone, O_3, which is reduced to the oxygen molecule O_2, at moderate temperatures, so at very high temperatures, and partially, perhaps, at low ones, the molecule may break up into its constituent atoms, and the increased heat required may be the necessary energy of decomposition.

PRIMARY BATTERIES FOR ELECTRIC LIGHTING.

THE history of primary batteries for electric lighting was very well recounted the other night by Mr. Isaac Probert before the Society of Arts, and with Mr. Probert in the chair, and all the inventors of the new batteries of which we have lately heard so much present, it was certain that a good many statements would be made which may or may not have been reasonable. Mr. Probert placed the facts clearly and forcibly before his hearers, and concluded by expressing the hope that the many inventors present would favour the meeting with fuller details of their batteries than he had been able to give in his paper. As a matter of fact, the inventors did give a great deal of information in the shape of assertion, but not much in the form of actual detail as to the working expenses of their batteries; and Mr. Preece was not difficult in pointing out that they claimed rather too much, although he acknowledged that he did not take so pessimist a view of the future of primary batteries as some people, for there was plenty of room for them, not only where dynamos and secondary batteries are out of the question, but also on the second economy. Still, it is quite clear that Mr. Preece does not believe in batteries which cost nothing, never require recharging, and the residuals of which are of great value. He has too many new batteries submitted to him to believe altogether in the statements of their inventors, and no doubt knows very well within what limits it is possible to make improvement. In commencing his paper, Mr. Probert alluded to the fact that the electric light was first produced by the aid of a battery more than 30 years ago, and that although it was produced much more economically by means of dynamos, there are many thousands who nowadays desire to revert to the old plan and confine their installation to the simple, if expensive, battery. There is some doubt as to who was the first to obtain the electric arc; but it has been commonly accredited to Sir Humphry Davy, who had a battery of 2,000 cells. Children constructed a battery of 20 cells with double plates 4ft. by 2ft., and obtained a very brilliant light; but as he used points of wood charcoal, because the modern hard carbons were then unknown, the light was unsteady, and the points quickly gave out, while as regulators were not then invented, the light was voted more trouble than it was worth. No progress of any importance was made until in 1836 Grove devised his nitric-acid battery; but the first great advance was made when Smee invented his constant battery, which was followed by Daniell's, to this day the best cell where a constant current is wanted.

With the invention of the Grove cell, the electric light received a great stimulus, and from that time to the present the electric light has been commonly used by lecturers and others for experiments. It was in 1831 that Faraday made the great discovery which is the foundation of all the modern dynamo machines, and with the introduction of the Gramme machine, the patent for which has now just about expired, electric lighting entered on a new phase. The Gramme was patented in 1870, and was then practically as good as now—an instance of how long it takes the owner of a valuable invention to make his discovery a profitable one, when he has to create a public demand. Since the introduction of the Gramme many dynamos have been devised; but, as for all purposes of practical utility they require power to drive them, history is repeating itself, and for the last two or three years there has been a more or less ardent search after batteries which should yield current without much trouble and at a comparatively small outlay. Those who are acquainted with the rudiments of the subject know very well that no battery can compete as to economy with a dynamo, unless the residual products are of commercial value, and even then they must be of such importance as to pay for the collection and the labour of charging the battery. According to Mr. Probert, making all necessary deductions and allowances, the quantity of zinc required per horse-power-hour of energy is 1·21lb., or for, say, 12½ horse-power-hours, 13lb. of zinc is needed. That at 2½d. per pound will cost 2s. 8½d., and the sulphuric acid required to oxidise it will cost at 1d. per lb. 2s. 3d. Add to the total expenses for the material necessary to charge the battery will be 1s. 11d. If nitric acid be used the cost will be, reckoning the acid at 6d. per lb. (p. 198), or, taking the Bunsen or Grove cell as the cleanest employed, the expense for acids and zinc amounts, on paper, to 8s. 6d. for 12½ horse-power-hours. But that is not all: a battery cannot be charged and kept in action until every bit of zinc is oxidised and every drop of acid is utilised. Mr. Probert says experience teaches that not more than 70 per cent. of the acid can be utilised. It is not, however, necessary to go minutely into the figures he gave. The best battery known to electricians for producing the electric light is the nitric-acid cell, and that we have seen costs 8s. 6d. (on paper) for the raw materials with which it is charged to give 12½ horse-power-hours. As a matter of fact, in practice it costs more, for the reasons above given; but take it at 8s., and compare it with a gas-engine which will give 12½ horse-power per hour for certainly 1s. 6d., and we see at once where the battery is in the scale of economy. It is not worth while to go into questions as to the cost of dynamo and the relative running expenses for different and smaller; for, as Mr. Preece regards the former, we may take it as about the same, and for the latter, the attendance on batteries will certainly cost more than on an engine and dynamo. However, taking the round numbers, the cost per lamp per hour, according to Mr. Probert, is 27 11/16d. 9d. in one case, and 47 9/16d. 5s. in the other. It is obvious, then, that where an engine and a dynamo can be employed, batteries are altogether out of the question; but we have reason to recognise the fact that many persons are desirous of employing the electric light on a small scale, and these of course are prepared to pay for it; hence it is an important question to inquire whether it is possible by any means to reduce the cost of primary batteries. As Mr. Probert said there are four ways in which it may be possible to accomplish that much-desired result: 1, by the employment of a cheaper oxidiser than sulphuric acid; 2, a cheaper oxidiser than sulphuric acid; 3, by the use of conductors for more completely exhausting the solutions; and 4, by the production and sale of useful residuals. In the first and the last of these methods it may be possible to do something to cheapen the battery current; but three is little scope for a possibility of improvement in connection with the second and third. Zinc is almost universally employed as the oxidisable substance, because it is, all things considered, the most efficient and convenient; but both lead and iron have been used, and Slater's iron cell is well known if rarely used. Hydrochloric acid has been employed in place of sulphuric, but with doubtful advantage; several methods of more completely exhausting the solutions have been tried, but as to the actual economy we know no knowledge; and as to the production and sale of residuals, it remains to be seen what is the price they fetch and what effect their production in quantity will have upon the market. The only novelty preserved by the Post-office is, we believe, the "black cell" from Daniell batteries, which contains a quantity of pure copper in the metallic state; but fromnearly 30,000 cells the sum spent last year by the use of the "black cell" was £67 14s., or a fraction more than a halfpenny per cell! As Mr. Preece pointed out, however, the battery is almost only relied on for the labour power employed by the Post Office, and the cells are only used when the gas or the dynamo fail. The actual supply of current required for telegraphic work is so small compared to that needed for lighting. Several of the batteries practically now batteries were shown at the meeting, and were described in the inventors' words by Mr. Probert. Those by Holmes and Burton battery, which we believe is engaged by some of the electric light companies, is noticeable for the facility with which the cells are charged and discharged, the cells being connected by siphons; for the former it is claimed that they are not liable to freeze; and for its cheapness, the cost of the solution being about 6d. a gallon, which is said to furnish 720 to 800 ampère-hours, at 1·5 volt, or M.F.D. 1·0 volt. The solution is prepared by dissolving nitrate of soda in saltpetre acid, and nitric acid is produced as required by the decomposition of the salt. Mr. Holmes's battery has carbon plates dipping into dilute hydrochloric acid as "Eureka," the zinc being in common salt. The cell of Oliver and Rice, which is a two-fluid bichromate, having zincs coated with a thin film of gold before amalgamation. The chairman, Mr. Preece, stated that no fewer than 150 patents for primary batteries had been taken out within the last three years, and specially mentioned that of Mr. Skrivanoff (see p. 82, Vol. XXXVI.) as remarkable for compactness and power. Mr. Holmes exhibited a model of his battery, and stated that the fumes from the nitric acid were converted into nitrate of ammonia by a solution of the sulphate, or were absorbed by a solution of sulphate of iron. Mr. Rice stated that any domestic servant could manage his battery without difficulty, for it is necessary only to daily remove about one-seventh of the solution and replace it by fresh acid, which is done by raising and lowering a tube, the battery working from two to three weeks without any more attention than that. The liquid is very cheap, being mainly water and hydrochloricacid, with a small quantity of a solution, the nature of which was a secret (hyponitric acid, see p. 209, Vol. XXXVII., p. 422, Vol. XXXVI.) Mr. Burt, in describing the battery made by his firm, states that the cost of zinc was "hardly worth considering" (!) The carbon cell is charged with a solution of 3½ parts by weight of bichromate of potash, 1 sulphuric acid, and 10 of water; the zinc cell has water only with about half an ounce of chloride of mercury. It would seem that the cloths made for this battery is that by its means water itself is oxidised (!), at least, so it was stated by Mr. Wharton, who also said that so bad used a battery on many occasions for real practical work and had found the useful and for superior to accumulators. All the statements made as to the capabilities of the batteries are to be taken with large grains of salt; for, as Mr. Preece said, batteries, though very nice for many purposes, are "expensive luxuries." His advice to the inventors, to apply experience to their batteries and bring forward the actual results, must have sounded rather ironical to the gentleman who can produce electricity for a mere trifle, but who do so only on paper.

Irene March 8.

The Engineer—Jan. 9, 1885. 135

NEW ELECTRIC ACCUMULATORS.—It may interest those who have been looking forward to a practical application of electric lighting to private houses and to a possibly general use of the enormous forces which, by the aid of electricity, are produced under costly circumstances in that great impediment have recently been made in electrical storage or accumulators. It is stated that these improved batteries store at one time the durability and possess 2½ times the storage capacity of those known as the Faure accumulators, and that they are of such a practical construction that they can be readily renewed at a trifling cost without waste of material, while their first cost is less than that of the Faure. Each cell, of about 43 lbs. of gross, will contain, and consisting of about 60 lbs. of metallic materials, is capable of containing 400 ampères, and of delivering during eight hours a current of 50. Each cell, in fact, represents over 1 horse-power of energy for one hour. Public demonstration will be made very shortly, and it is stated that probably within a few weeks, at the Crystal Palace Electrical Exhibition, 500 incandescent lamps will be shown running upon one set of 25 large cells of this new zinc carbon.—*Times*.

SECONDARY BATTERIES.

SIR,—On the 10th ult. you published an article on the electrical locomotive recently built by the Storage Company, in which you gave certain figures as to the weight of the cells, which are likely to be misleading. You say that owing to the designs lately introduced, the useful output for a given weight of cell is almost without limit—my way meeting the durability and but, that the durability has been increased by the new designs, and that the cells used for lighting purposes would depreciate in the same ratio, which is far from the case.

The type of plate manufactured by the Storage Company enables the conductor and the active material to be disposed for the best advantage, but the properties are varied according to requirements. The accumulators supplied for lighting purposes are made with a view to large output, and are usually supplied with a high effective return, whereas in the locomotive the first consideration is a rapid discharge from a minimum weight of cell, and the active material is distributed where most needed, but the same durability cannot be expected as with cells designed for lighting or other purposes where weight is of minor importance. We have every reason to believe, that Mr. Reckenzaun's allowance for depreciation is not at all too much, as the cells which were first made have been in constant use for over three months and show no signs of deterioration.

It is impossible to say definitely what the 25s will be of the plates manufactured for lighting purposes with the latest improvements, but it may be mentioned that with the older types the positive plates have lasted eighteen months, and there is little doubt that this will be exceeded when the new plates are supplied.

The depreciation is another element entirely open to criticism, and the company has already made arrangements with their customers in this respect by quoting a special price for renewal plates.

UNDERGROUND CONDUITS.

Views of a Practical Electrician and Telephone Manager.

Cincinnati is negotiating the placing of telegraph and telephone wires in that city underground. In a recent interview in the *Times-Star* of that city, Captain G. N. Stone, the General Manager of the Bell Telephone Company had this to say on the subject:

"We are all interested in the subject of underground conduits, not only for the reason that legislators have undertaken to compel telegraphic and telegraph companies to make use of them, but because, also, that they would be a great saving to us in the care of our wires and in rendering the use of expensive poles unnecessary. The trouble is that no conduit has yet been devised which meets the requirements.

"A year ago the Legislature of New York passed a law making it obligatory upon all telephone and telegraph companies to conduct their wires through the large cities of the State beneath the surface of the ground, and provided for the appointment of a committee of 100, to consist of the Governor of the State, the Mayor of New York City and the most eminent electricians in the country, to recommend to the Legislature a suitable plan by which wires should be so stored for. The committee was organized and various sub-committees were appointed, and one of them has just reported the result of an investigation made of all the devices for underground conduits patented. They say that they examined over 600 devices, but did not find a single one which was entirely satisfactory. In the report it is said:

"'As regards a conduit, the principal requirements are that it be cheap, water-tight, have sufficient capacity, to permit (without disturbing the pavement) the insertion, removal and addition of wires, and allow access for repairs and testing.

"'No system submitted or investigated by the committee seems to fulfill all the requirements as satisfactorily as a properly constructed tunnel of sufficient size to admit the passage of workmen and access to the wires within it. Connecting with this tunnel, conduits of sufficient capacity for lateral wires could then be constructed as described. The multiplicity of subterranean structures in this city might tend to operate disadvantageously, if not to prohibit the construction of such a tunnel, unless the same were arranged to accommodate the gas, steam and other systems, as well as the electric wires. The deteriorating influences of steam and gas would, however, be met, by destroying or impairing any system of insulation, or the conduits in the lower portion of the city questionable.'

"You see that the nearest approach to perfection is the tunnel, which would be very expensive and practicable, and would probably not answer even then. In fact, I do not think the tunnel system would do at all. I have received advices from a gentleman in London, England, in whose statement I have entire confidence, that all the telephone wires in Paris, France, which were carried through the enormous sewers of that city, have been taken from them and are now strung along the tops of the houses. So we have no recourse except to the poles. It is not right that legislators should attempt to force us to carry our wires underground until some way has been presented by which we may do so. Speaking for my own company, I can say that it is willing to resort to conduits when a satisfactory one shall be offered, but we must not be arbitrarily ordered to put our wires underground until then. It would not be just to compel us to spend our money in making experiments. Why, it costs us yearly many thousands of dollars to keep our wires in proper condition. Wires get rusted and broken, poles rot and have to be replaced, and men must be employed. We keep a standing force of twenty-five men whose duty it is to repair the lines. All this expense would be obviated by a reliable conduit."

Steam Engine Tests at the Electrical Exhibition.

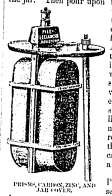
The Franklin Institute has tests proposed for steam engines at the International Electrical Exhibition. The conditions of exhibition and test are very simple and, on the whole, likely to give satisfaction. Exhibitors desiring quantitative tests made of their engines must send in formal application before July 15. Competitive tests will not be made, save on the joint application of two or more parties desiring them, and the competing manufacturers must, previous to the tests, agree on the rating of the various points of the engine, subscribing to the code and agreeing to abide by the decision of the judges without appeal. The code is in two sections: conditions of exhibition and test; and preparations for the tests.

The Leclanche Battery.

The accompanying cuts illustrate the Prism Battery, designed and patented by the Leclanche Battery Company, of New York, and which may be fairly said to be the most standard telephone battery of the world, over 1,000,000 being in use in Europe, and over 500,000 in the United States. The cause of its great popularity is that it has been found to completely fill the need created by the telephone for an efficient working battery for open circuit work. The introduction of this battery was simultaneous with that of the telephone but the Leclanche Company have added many improvements from time to time, and it is those which we illustrate. The latest of these is a new form of jar and cover for the well-known Prism Battery. The cover rests

PRISM BATTERY, COMPLETE.
Size of Jar: 6x3(3/4 inches; height, 6½ inches.

upon a shoulder inside of the jar which is oval in shape, the rims of the jar above the cover being concave in shape. The cover when in place, closes the jar sufficiently tight for ordinary purposes, but if desired, it may be hermetically sealed. To do this: soften a little paraffine wax to about the consistency of putty, and with it fill in any space between the cover and the jar, and also around the carbon and zinc, in order to prevent the melted wax from running down into the jar. Then pour upon the cover melted wax, which will spread over the cover, settle in the concave rim, and effectually seal the jar. After sealing, raise the zinc rod, to loosen it in the wax. This will leave sufficient space around it for ventilation, but not enough to permit the slopping over of the liquid. Whenever necessary to clean or renew the Battery, the sealing material can be removed with a knife-blade.



PRISM, CARBON, ZINC, AND JAR (OVAL).

The Leclanche Prism Battery possesses the unquestionable advantage of dispensing with attention during long periods of service, provided: that it be used only for those purposes for which it is suited and for which it was intended. It is an Open Circuit Battery, and is not intended for Closed Circuit work. By Open Circuit work is meant that requiring the closing of the circuit temporarily and for short periods only, such as services on Telephones, Call Bells, Gymnasium Work, Burglar Alarms, etc., etc. No internal action takes place in the Leclanche Battery unless the Circuit is closed, so that when not actually at work there is no consumption of materials, and the Battery will last indefinitely. As the highest use of the Battery the length of the periods during which the Circuit may remain closed, without injury, varies with the amount of resistance in the Circuit.

The less the resistance, the greater will be the tax on the Battery, and the shorter the time required to exhaust the elements. The greater the resistance, the less will be the tax on the Battery, and the longer will be the term of service.

With a high resistance it may be used for purposes requiring the closing of the Circuit for a half hour or more at a time.

The same Company also manufacture the Leclanche Plaque Cell, which, until the introduction of the Leclanche Prism Cell, was the best open circuit battery made, and the one most generally in use both in this country and in Europe. It is still used to some extent, and, as made by the Leclanche Battery Co. of the best materials and with care and skill, is an efficient and useful battery. It has, however, defects from which the Prism Cell is entirely free and is fast being superseded by the latter.

The Leclanche Batteries are made by skilled workmen, of the best materials, and these facts together with the able business management of the Company, have won for them their present great popularity.

The instruments of the Anti-Bell Telephone Company of Boston are sold outright, not rented. Being mechanical, they do not infringe on the Bell patents. They work satisfactory for a mile.

ONE OF THE ELECTRICAL PROBLEMS.

In his investigations relating to storage batteries, Mr. Edison has discovered, it is said, nevertheless that, at present, little is known in regard to the age of plates—that a year, only, is considered a fair average, this being the time in which they are found to last for service. Think plates are found to last for much longer than this, which is quite unusual, considering that the wasting out is due to rust also, and that the latter is prevented, as has already been remarked, that the internal positions of a thick plate are to a great extent protected by the outer layers, which are, of course, the first to begin rusting. And as it must, also, be remembered, that the cost of material is far more than the cost of manufacture, that the material reserved has a market value not inconsiderable, and that the process of reducing and purifying such which plates have to be renewed is not such as to cause much inconvenience, it would appear that the age of plates, as at present manufactured has been over-estimated. Many users, for think, may be hoped for in this direction in the future—in fact, that a well-chosen, properly charged and fully treated plate will be found to last many years, and therefore it becomes distinguished. Incidentally, in the types of cells, adapted to different purposes, are also to be looked for.

Carbon

Un appareil Morse monté *en duplex* est un peu plus rapide qu'un appareil Hughes; il est vrai qu'il demande un nombre double d'employés, mais ils peuvent être mêlés expérimentés; le Hughes étant un appareil délicat, est d'ailleurs fatigant à manier.

D'un autre côté le Morse se monte *en duplex* très-facilement; on a imaginé au poste central un moyen commode, basé sur ce fait que les électro-aimants ont deux branches : au lieu de contrarier deux fils sur une tige, on a contrarié les tiges l'une par l'autre; aussi, pour les lignes courtes et chargées de trafic, emploie-t-on maintenant très-fréquemment ce système *en duplex*. Je dis pour les lignes courtes, car pour celles-là on peut se passer du condensateur, et comme M. Stalrus, qui en a inventé l'emploi, fait payer le plus cher qu'il peut l'usage de son brevet, ce qui est naturel en vendu à l'employer; les télégraphistes, de leur côté, préfèrent les moyens les moins coûteux, et cela est naturel aussi, c'est pourquoi avant de mettre *en duplex* sur les grandes lignes, on emploie des appareils plus rapides que nous passerons en revue dans un prochain article.

FRANK GERALDY.

RECHERCHES NOUVELLES

SUR LA THÉORIE DU MICROPHONE

3e article (Voir le nº du 15 novembre).

1 Dec 1879

Dans le précédent article on a établi que, pour que la transmission des sons articulés fût possible, il fallait que le nombre des points de contact, les différences de ce nombre pendant l'action de l'appareil et les changements de résistance qui en résultent fussent les plus grandes possibles.

C'est dans ces conditions que sont disposés le microphone du modèle principal de M. Hughes, le téléphone à charbon de M. Ralloni, le téléphone transmetteur avec deux crayons de graphite de MM. Pollard et Garnier, de M. Helleseo, etc. La forme représentée ci-dessous peut nous servir comme

type d'explication pour toutes les autres, et je la regarde aussi comme très-commode dans toutes les expériences microphoniques. Elle peut être employée pour la transmission de la parole, du chant à divers degrés d'intensité, du bruit d'une montre placée à côté, d'une mouche placée au dedans, de la musique d'un piano, etc. La membrane en de caoutchouc, bien tendue, et pourvue d'une mince bande de papier d'étain pour unir le charbon de dessous avec le bouton d'attache.

Il est facile de remarquer que pendant les vibrations de la membrane, une plus ou moins grande quantité de points de contact réunit les deux électrodes microphoniques, ce qui nécessairement produit des changements de résistance. Par le fait de l'introduction du microphone dans le circuit, cette résistance augmente considérablement, et réduit la force du courrant à 1/1ᵉ et plus de son intensité primitive. Les vibrations mécaniques de la membrane peuvent la reconnaître en partie ou la diminuer encore, et, quoique ces changements soient bien petits, ils présentent cependant, *grâce à leur rapidité*, une quantité d'inflexions qui permettent de reproduire toutes les nuances de la voix.

Si je ne me trompe, l'influence de l'énergie des ondes sonores sur l'intensité des sons perçus dans le téléphone, n'a pas été encore reconnue positivement. Au contraire on était porté à croire qu'elle ne devait pas exister (Voy. Clerk-Maxwell, *Nature*, vol. 18, p. 162) (1), et cependant il n'est impossible d'en douter. Seulement il faut prendre en considération non pas le côté sonore, mais le côté mécanique des phénomènes. Quand on parle à voix basse près du microphone, ou à voix forte mais à une distance de quelques mètres, les sons sont plus faibles que quand on parle à voix haute ou de près. Une montre à bruit fort est mieux entendue qu'une montre à bruit faible, etc. Les limites de proportionnalité sont bien restreintes, il est vrai, mais les différences de résistance le sont aussi. Augmentons celles-ci, et nous changerons celles-là.

La prétendue indépendance des sons du récepteur de ceux qui frappent le transmetteur a pris sa source dans un fait parallèle au premier, savoir, que les limites d'une articulation *distincte* sont beaucoup plus rapprochées que celles des sons non articulés. *La distinction* et la netteté *des consonnes transmis par un microphone, sont en raison inverse de leur intensité. L'intensité croît à mesure que les vibrations microphoniques tendent à interrompre complétement le courant, tandis qu'en même temps la faculté de transmettre les sons articulés disparaît.*

Et c'est là la principale difficulté qui empêche d'amplifier les sons à volonté.

L'intensité des sons acquiert son *maximum* lorsque les interruptions du courant deviennent complètes; mais alors les sons ne peuvent plus être articulés; voilà pourquoi on entend mieux quand on parle d'une voix ordinaire, que quand on parle d'une voix basse.

L'intensité des sons est aussi en rapport direct avec la force du courant, mais ce rapport est encore plus réduit que les précédents. Les manifestations microphoniques commencent dès que le courant a la force de vaincre la résistance du microphone et de le traverser. Ce sont les bruits d'interruption complète qui se manifestent les premiers; ils sont très-faibles, et leur modulation est encore impossible. Si on augmente l'intensité du courant, la modulation acquiert son premier degré, et le bruit d'une montre en perçu nettement. Il devient plus fort à mesure que l'intensité du courant fait

(1) M. Wroblewski, professeur à l'université de Strasbourg, fait mème de cette négation une loi en disant que « l'énergie des ondes sonores n'a aucun rapport avec l'intensité des sons perçus ». (*Comptes rendus*, 1876, T. 3ch. Lehnergt.

lin poussant la rédaction du téléphone encore plus loin, on peut arriver à se passer du microphone récepteur et même d'une bobine électrique, en appliquant de simples électrodes (lames ou cylindres métalliques) contre les deux tempes. Le courant intermittent passe alors par la tête, et la peau sèche joue ici le même rôle que les feuilles de papier dans le condensateur chantant de MM. Varley et Pollard. On peut aussi construire une harpe électrique avec des fils fins, rapprochés les uns des autres, et cette harpe émet des sons quand elle est traversée par un courant discontinu. C'est alors l'air qui joue le rôle du nouveau conducteur. Enfin, une spirale de fil fin engendre des sons sous l'influence des attractions électrodynamiques.

Il ne nous reste plus qu'une remarque à faire sur les propriétés thermométriques du microphone. Elles rentrent dans le même ordre d'explications que celles qui nous ont servi pour comprendre l'action du microphone agissant comme transmetteur; seulement comme il s'agit ici d'une action électromotrice et non téléphonique, les changements dans les points de conductibilité n'ont plus besoin d'être *rapides*. Une autre différence, en apparence contradictoire se fait remarquer. On sait que le *microtasimètre* de M. Edison présente des effets tout à fait opposés à ceux du *microphone thermométrique* de M. Hughes. Dans le premier, la chaleur agit par une augmentation de conductibilité; dans le second, c'est l'inverse : la chaleur augmente la résistance. Pourquoi? Parce que, dans le premier cas, s'est un corps *solide* qui se dilate sous l'influence de la chaleur, en *augmentant le nombre des contacts*, tandis que dans le second cas où il existe plusieurs petits morceaux de charbon juxtaposés, c'est *l'air*, qui les entoure et les sépare, qui se dilate avant tout, et cette dilatation doit nécessairement produire une *diminution dans le nombre des contacts*; mais le principe reste toujours le même.

En résumé, il nous est impossible de reconnaître dans le microphone une nouvelle propriété de la matière, en, tout au moins, celle de l'action directe des ondes sonores sur certains corps médiocrement conducteurs. Le microphone ne présente aucune analogie avec le *microscope*, et sa théorie n'a aucun rapport avec celle du *silénium*, ce qui cependant n'empêche pas l'invention de M. Hughes d'être une des plus grandes de notre siècle.

La seconde théorie, celle de la pression, n'est de même qu'une exposition superficielle des faits, et, à notre avis du moins, elle doit être abandonnée.

Dr Julius Ochorowicz.

RECHERCHES NOUVELLES

SUR LA THÉORIE DU MICROPHONE

Déc 15 1879

Deux hypothèses principales ont été émises pour expliquer les phénomènes que présente l'ingénieuse découverte de M. Hughes.

L'une, exclusivement moléculaire, suppose des dilatations et contractions des molécules dans certains corps médiocrement conducteurs, sous l'influence des vibrations sonores, au sein même du microphone. Les *changements de densité* deviennent correspondre à des affaiblissements de résistance ou d'un affaiblissement, et conséquemment, à une production proportionnelle des sons. Cette hypothèse présente une certaine analogie avec les phénomènes que manifeste le sélénium sous l'influence de la lumière et de la chaleur rayonnante.

L'autre, en partie moléculaire et en partie mécanique, repose sur la découverte faite il y a longtemps par M. du Moncel, et suivant laquelle les accroissements et les affaiblissements de résistance tout dus à des *changements de pression* dans les points de contact électrique. Ces changements étant produits par la pression de l'air vibrant, il en résulte une équivalence de causes et d'effets.

Si on ne tenait sur des expériences faites sur une multitude de microphones, depuis la première apparition de cette découverte, je tâcherai de prouver que, si l'une de ces hypothèses est tout à fait erronée, l'autre n'est vraie que superficiellement.

Commençons par la première :

1) Quand on humecte la baguette de charbon avec une colle quelconque, de la cire par exemple, sans lui faire subir la moindre pression, le microphone reste muet sous les plus fortes influences sonores, ce qui serait impossible s'il ne s'agissait ici que de mouvements moléculaires et non mécaniques.

2) On peut enfermer le microphone dans une tube de verre suspendu légèrement au moyen d'un fil fin, et faire le vide dans ce tube, sans paralyser les effets microphoniques. Il est évident que, dans ce cas, les molécules d'air ne peuvent avoir aucune influence sur la densité du charbon ; elles n'agissent que mécaniquement en ébranlant l'appareil tout entier.

3) Il est impossible de construire un microphone d'un seul morceau de charbon solide, présentant des contacts stables, ce qui n'empêche pas les influences moléculaires, mais ce qui rend impossible l'action des ondes sonores, des ébranlements et des ébranlements quelconques, sur le courant qui traverse le charbon.

Il me semble donc, que nous avons là des raisons suffisantes pour rejeter toute théorie exclusivement moléculaire.

Passons à la seconde :

1) La pression latérale exercée sur un conducteur électrique compact (métal, charbon, etc.), placé dans un téléphone, n'engendre aucune action microphonique.

2) Une pression longitudinale exercée sur la baguette d'un microphone au moyen d'une vis de réglage, peut être modifiée entre certaines limites, sans altérer le fonctionnement de l'appareil. Ce n'est que le timbre qui change alors d'intensation. Mais le même effet peut être obtenu sans changement de pression, par le seul fait du déplacement des points de contact. Si l'on continue d'augmenter la pression, l'appareil perd de sa sensibilité, en même temps qu'il perd de sa faculté de vibrer mécaniquement ; mais le fait seul d'une augmentation de pression ne se rapporte à aucun phénomène microphonique. (Cette expérience est à faire avec un microphone à membrane.) »

1) On peut construire des appareils dans lesquels la pression reste la même, et qui cependant agissent comme microphones, (Voir plus loin.)

Il est donc rationnel de ne pas considérer la pression comme cause essentielle des phénomènes microphoniques.

Elle en est cependant une cause accidentelle, car quand les ondes sonores frappent la partie mobile de l'appareil, la pression qu'elle exerce sur son support change; mais ce n'est pas du fait de la pression que résultent les différences de résistance ; c'est un autre fait, souvent parallèle au premier, mais qui n'en est pas moins différent.

Pour le mieux apprécier, considérons l'appareil dans sa forme la plus simple qui est celle de la figure 1.

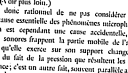

Fig. 1.

Deux bouts de fil métallique réunissant dans leur circuit la pile et le téléphone, sont tendus en croix l'un sur l'autre : le courant passe au point de croisement. C'est *à ce point seul* que se concentre l'action microphonique. Quand on fait vibrer l'un des fils par une cause quelconque, un bruit ou un son musical très-intense se fait entendre dans la salle où est placé le téléphone. Si les fils sont bons conducteurs, l'action de l'appareil n'a que deux phases : le courant passe quand un fil touche l'autre, il ne passe pas dans le cas contraire. Il n'y a donc là qu'une *simple et complète interruption du courant*; et, en conséquence, ce microphone, comme le transmetteur du téléphone de Reiss, comme celui du chanteur de M. Pollard, etc., ne peut transmettre que des sons simplet. Cette première catégorie embrasse tous les microphones dans lesquels le contact s'effectue par un seul point. J'ai obtenu les meilleurs résultats de ce genre avec une membrane de vessie tendue et une pointe d'acier. La communication électrique était assurée par une petite bande de papier d'étain collée sur la membrane. Avec un petit élément à bichromate de potasse, le chant a pu être entendu dans toute une chambre.

Sinconsistent parlant, il y a, dans ces simples appareils, quelques nuances d'action entre les limites d'intensité complète et de rupture complète du courant, et on peut considérer qu'il existe deux ou trois réglages pour lesquels *l'interruption n'est que partielle*.

C'est donc le changement des points de contact qui joue ici le rôle principal. Du nombre plus ou moins grand de ces points, dépend *l'intensité* des sons; le nombre des interruptions successives des mêmes contacts détermine leur *hauteur*, et les changements successives leur *timbre*; enfin des diverses combinaisons successives et simultanées, périodiques ou non périodiques, *devient ces différents* résulte leur *articulation*. Il suffit de comparer les traces de la parole dans le phonautographe, le logographe et le phonographe, pour se convaincre qu'il n'y a en réalité, dans ces appareils, qu'une *réduction de la qualité en quantité*. Je suis même porté à croire que cette réduction est bien simple, et qu'une série de combinaisons en temps et en espaces *de trois points matériels de contact*, suffit pour servir d'équivalent à tous nos sons articulés. Il me serait difficile de rapporter ici toutes les expériences et réflexions qui m'ont conduit à cette supposition. Je attendant, je me la donne qu'à titre de probabilité, et je passe à la troisième catégorie.

Le principe du changement dans le nombre des points de contact provoqués par la pression, nous permet de considérer les différences résistances du circuit microphonique, comme si le fil qui le compose devenait tantôt plus gros, tantôt plus fin, et explique l'action de la plupart des microphones, mais il en est qui explique pas tous.

On peut construire, en effet, des microphones dans lesquels il ne peut se produire aucun changement de pression ni, même, aucune variation dans le nombre des points de contact, et qui cependant fonctionnent bien.

Fig. 2.

Supposons un petit cylindre de charbon *a* (fig. 2) collé perpendiculairement à une membrane MM et glissant sur un autre petit cylindre de charbon *b* mobile autour de son axe. Si la forme cylindrique de ces deux morceaux est parfaite, la pression et le nombre des points de contact restent les mêmes. S'il en est autrement, comme cela a lieu dans la pratique, ce n'est plus cet effet qui joue le rôle principal : c'est la *longueur de la route traversée par le courant dans le nouveau conducteur*. Pendant que la membrane vibre, son éloignement du charbon *b* diminue ou augmente, en effet, et il y a donc un changement dans le nombre des points de résistance traversés.

C'est à cette classe d'appareils qu'appartiennent aussi les téléphones transmetteurs à liquides de MM. Gray, Bell et Salet, où le changement de résistance dans le circuit résulte d'une couche de liquide plus ou moins épaisse, qui doit être traversée par le courant.

Il est bien difficile de séparer les deux principes l'un de l'autre, mais il est possible de déterminer la prépondérance de l'un ou de l'autre, ou bien encore leur parallélisme. Supposons, par exemple, que les deux cylindres de charbon *a* et *b* soient remplacés par deux lames de la même matière, et que *b* reste immobile : les deux actions seraient égales et

charge s'écoule en dehors. D'après Faraday, l'effet ne produirait exactement comme si un fil métallique avait été substitué à la chaîne de particules attirbuées doublant la charge électrique. (*Voir ses Recherches expérimentales*, série XII, p. 1406.) Toutefois, la plupart de ces essais ne furent pas satisfaisants.

« On fit alors de nouvelles expériences avec des plaques dites *paraffinées*. L'un des premiers systèmes de ce genre était constitué par une plaque de cuivre mise en communication avec la terre, et par une autre plaque reliée à la ligne; ces deux plaques étant isolées l'une de l'autre, au moyen d'une feuille de papier ou de mica mince imbibée, la feuille, chauffée pour le fil, percé alors la papier, et s'écoule directement en terre au lieu de passer à travers les fils des appareils télégraphiques.

« Une importante modification fut apportée à ce système par M. W. Siemens, en conseillant ou en rayant les faces des deux plaques opposées l'une à l'autre, et en les plaçant l'une sur l'autre, de manière que les rayures se croisassent à angle droit. De cette manière, les plaques régulièrent comme si elles avaient été pourvues d'une infinité de petites pointes métalliques, et ces pointes devaient naturellement faciliter la décharge. Cette action est, de reste, bien connue, et son application aux parafoudres est indiquée dans les *Annales de télégraphie* de M. C. Walker, F. R. S.

« Le système Siemens, très-ingénieux en théorie, ne réalisa pas, toutefois, les effets avantageux qu'on attendait son auteur, et il ne présenta pas d'avantages marqués sur les autres systèmes. Cela tenait à ce que les pointes qui devaient résulter mathématiquement du croisement des rainures n'étaient pas formées physiquement et microscopiquement, et c'était de leur action que les effets protecteurs devaient résulter.

« Le Dr Warren De la Rue ayant mis simultanément à ma disposition sa batterie composée de 10000 éléments, je voulus éclaircir cette question, et j'y préparai deux systèmes de doubles plaques identiques comme dimensions, et la seule différence qui pouvait exister entre les deux systèmes, consistait en ce que, dans l'un, les plaques étaient cannelées, et que, dans l'autre, elles ne l'étaient pas; elles étaient d'ailleurs séparées par des bandes circulaires d'ébonite ayant 0,01 de pouce d'épaisseur. Les plaques de chaque système étaient reliées en communication avec le pôle positif de la pile, les autres plaques avec le pôle négatif, et le nombre des éléments de la pile était augmenté successivement jusqu'à que l'on pût obtenir un courant non interrompu; j'obtins alors les résultats suivants :

1° *Avec les plaques unies:*

Pour 1000 éléments	petites étincelles.
Pour 1080	étincelles visibles.
Pour 1700	étincelles fréquentes et nombreuses.
Pour 1800	arc continu.

2° *Avec les plaques cannelées:*

Pour 1000 éléments	étincelles n'apparaissant qu'au moment de la fermeture du circuit.
Pour 1080	étincelles visibles.
Pour 1300	étincelles fréquentes.
Pour 1800	arc continu, mais capricieux.

Avec 2000 éléments, on obtenait un courant continu dans les deux cas; mais avec 1300 éléments, l'effet produit était certainement plus marqué avec les plaques unies qu'avec les plaques cannelées, et nous prîmes considérer les résultats obtenus comme décisifs.

« On peut donc conclure de ces expériences que les rayures, ou cannelures, des plaques des parafoudres de cette nature, sont nonseulement inutiles, mais plutôt nuisibles aux effets préservateurs qu'elles sont appelées à produire.

« Les expériences précédentes ont, du reste, parfaitement confirmé l'exactitude des chiffres donnés par M. Warren De la Rue et par M. Stallet, dans leur communication à la Société Royale (1), sur la distance explosive des étincelles entre deux disques, — distance qu'ils fixent à 0,013 pouce avec 1300 éléments en tension et à 0,02 avec 1000 éléments.

(1) (Voir les *Proceedings* de la Société Royale, v. p. 169-172.)

« On emploie dans la pratique, au *Post-office* notamment, pour maintenir l'isolation des plaques, du papier paraffiné ayant seulement 0,002 pouces d'épaisseur. Dans ces conditions, la différence des potentiels sur les deux plaques est seulement de 280 volts.

« MM. De la Rue et Muller ont démontré que des différentes sortes de surfaces à opposer les unes aux autres, y compris même les pointes, c'étaient les surfaces planes qui exerçait le plus grand effet, du moins pour un potentiel ne dépassant pas 1300 volts, et que les pointes ne sont efficaces que quand ce potentiel est considérable; et, comme il est douteux que l'électricité atmosphérique ait un potentiel supérieur à celui qui serait développé sur un fil télégraphique par une source électrique de 1000 volts, on peut en conclure que les surfaces planes et unies, séparées par une couche isolante de 0,002 d'épaisseur, donneront les meilleurs résultats pour les parafoudres. »

W. H. Preece.

EXPÉRIENCES DE M. R. COULON

SUR LE CONDENSATEUR CHANTANT

—Telephone—

Le téléphone n'est pas, comme certains appareils, sorti d'un hasard heureux ou du tâtonnement d'un esprit simplement ingénieux. Il est, au contraire, le fruit de longues et persévérantes recherches, en même temps que le couronnement logique d'un système précongu.

Néanmoins, lorsque l'instrument a été livré à l'expérimentation et à l'étude générale, il a bien fallu reconnaître que les idées qui avaient conduit à sa réalisation ne pouvaient expliquer son fonctionnement. Ce fait n'est pas rare; beaucoup d'inventeurs illustres ont ainsi puisé leurs découvertes dans des hypothèses, sinon fausses, au moins inexactes ou insuffisantes et l'étude faite par d'autres de leur œuvre a révélé souvent bien des côtés inaperçus. Ainsi pour le téléphone, l'idée des attractions exercées par l'aimant sur le diaphragme et le mettant en vibration dut être bientôt écartée, l'explication était à trouver.

Dès l'origine, notre maître et collaborateur M. Du Moncel reconnut dans ces faits un phénomène d'ordre nouveau, un genre de vibrations différent des mouvements jusqu'alors considérés comme sonores ou magnétiques, une nouvelle manifestation de ces modifications internes, moléculaires, que les variations électriques font naître dans les corps.

Nous ne reviendrons point sur l'ensemble de ces recherches, le lecteur en trouvera les points saillants exposés dans ce Journal, numéro du 15 mai, par M. Du Moncel. Nous rappelons seulement ici la question, afin de donner l'importance qu'elles méritent aux études nouvelles faites sur ce point par M. R. Coulon, études qu'il a publiées dans le journal *l'Électricité*.

Dans le cours de ces recherches, les divers expérimentateurs ont naturellement employé différentes méthodes. Les uns, comme M. l'abbé Laborde, prenant le téléphone lui-même, ont fait varier la position et la nature de ses organes; d'autres, comme M. Hughes, M. Ader et M. Du Moncel, ont cherché parmi ces organes ceux qui étaient essentiels et ont réduit le téléphone aux formes les plus incroyablement simples.

M. Coulon voulut obtenir l'appareil non le plus simple,

point le condensateur, mais la distance entre sa surface et celle de ce dernier est variable et peut être mesurée.

La nature de la plaque peut changer sans modifier les principales conditions du phénomène.

L'appareil étant ainsi disposé, le condensateur est mis en jeu et, à l'aide d'un dispositif électrique ou d'un interrupteur bien réglé, on fait rendre un son constant. On peut alors découvrir les deux faits suivants :

1° Si l'on présente une plaque dont la distance au condensateur soit graduellement diminuée, à un certain moment cette plaque entre en vibration et rend un son *autre que celui du condensateur*, ce son augmente d'intensité et change d'acuité d'une façon régulière; à mesure qu'on s'approche, l'acuité s'élève continuellement, l'intensité, après avoir passé par un maximum, diminue de façon à ce que le contact le son, que M. Coulon nomme son secondaire, s'éteint.

2° La distance au condensateur étant constante, si l'on fait varier l'épaisseur de la plaque, le son varie en même temps. M. Coulon le démontre de l'élégante façon que voici : l'ensemble étant disposé horizontalement, il pose sur la plaque en expérience une cuvette carrée à photographie et produit la vibration il y verse de l'eau; à mesure que le niveau s'élève, le son se modifie.

Il résulte immédiatement de cette expérience, que c'est la plaque elle-même dont la vibration produit le son et non l'air interposé en tout autre corps. Cette conséquence très-importante se vérifie d'une autre façon. "

M. Coulon mesure les distances de la plaque au condensateur qui correspondent aux sons successifs d'une gamme. Il en forme une courbe et la compare avec la courbe connue des longueurs des cordes vibrantes produisant les mêmes sons. Ces deux courbes ne sont pas identiques, la différence est d'autant plus grande que la plaque est plus rapprochée du condensateur.

Il reste à déterminer par une série assez nombreuse d'expériences quelle est l'influence réciproque de la nature, de l'épaisseur des plaques; ce que M. Coulon se propose de faire.

Il nous restera à parler d'autres expériences dans lesquelles M. Coulon a étudié les sons en leur faisant produire des manifestations lumineuses. Cette série n'apporte pas beaucoup d'éléments nouveaux, elle est surtout très-brillamment démonstrative. Nous y reviendrons prochainement, mais l'ensemble des remarquables expériences qui viennent d'être décrites porte avec lui sa conclusion sans qu'il soit besoin d'attendre. Il en était que nous avons lu une confirmation nouvelle, méthodique, des théories émises par M. Du Moncel; nous retrouvons sous des formes très-diverses — très-brillantes et très-pittoresques — la démonstration de la transformation des vibrations électriques en vibrations moléculaires devenant sonores dans certaines circonstances. Essayer de dire dans lesquelles serait certainement prématuré, et pourtant nous ne sommes point sans lumières même sur ce point. On se souvient des expériences de MM. Govi et Duter, où il fut établi que dans certaines conditions de charge électrique les corps subissaient des changements de volume et pouvaient éprouver ainsi des dilatations et des contractions très-sensibles. M. Righi, en étudiant ces phénomènes, les relie au condensateur chantant par l'expérience suivante : « *Je fais observer, dit-il, que le curieux phénomène de Varley, du condensateur chantant*, peut s'expliquer par des dilatations instantanées à chaque charge et décharge; du moins cette dilatation est une des causes du phénomène, car, ayant mis en communication un de mes tubes à armature de mercure avec le fil induit d'une bobine dont le circuit inducteur était périodiquement interrompu par un diapason, le tube a reproduit le son par des vibrations longitudinales ». (Comptes rendus de l'Académie des sciences, 16 juin 1879.) Nous saisissons là sur le fait la transformation de la vibration électrique en vibration extérieure et sonore. Le fait peut n'être pas visible dans le condensateur, il y est presque prouvé. Comment cela se relie-t-il au téléphone, de quelle façon les condensations s'y produisent-elles? on ne saurait formuler l'hypothèse mieux que ne fait M. Coulon lui-même, dont les paroles seront notre conclusion.

« Je remarquai que si on réduisait un condensateur à sa plus simple expression, c'est-à-dire à deux surfaces conductrices infiniment petites séparées par une lame isolante, le chant était reproduit.

Mais deux surfaces infiniment petites ne sont autre chose que les extrémités de deux pointes, la lame isolante peut être une lame d'air : or, j'ai démontré expérimentalement que deux pointes placées en regard l'une de l'autre suffisaient à reproduire le son.

Mais nous savons aussi que l'épaisseur des lames est sans influence. Supposons les extrémités des pointes sans aucune épaisseur, elles se réduisent à un point : donc, une série de points séparés par des lames d'air reproduisent le son.

Le point réduit à l'infini, c'est l'atome; la lame d'air réduite à l'infini, c'est l'intervalle moléculaire. Or, les corps ne sont composés que d'atomes et d'intervalles moléculaires.

D'où je conclus qu'un corps n'est en réalité qu'un condensateur réduit aux dimensions atomiques. »

FRANK GUALTIER.

Electrician May 25, 1881

THE TELEPHONE AND THE FAIR SEX.—The introduction of the telephone by the Viceroy of Egypt into his palaces and harems has struck terror to the hearts of the fair occupants. They imagine that this is a dodge of his sovereity to keep himself acquainted with all their tittle-tattle and doings.

LONG-DISTANCE TELEPHONING.—From America it is reported that the telephone has been worked between Bangor, Me., and St. John's, New Brunswick, a distance of 214 miles. Every word is said to have been heard distinctly. We also hear that Vicksburg is connected with New Orleans, a distance of 230 miles, and that conversation is carried on with much distinctness.

Electrician 28 May 1881

Téléphone à résonateur de M. Edison.

On sait que, dès l'année 1865, M. Cecse, en pressant plus ou moins de la pinchbeck dans un tube par l'intermédiaire d'une tige à piston, était parvenu à faire varier entre des limites assez étendues la résistance d'un circuit dans lequel le tube était interposé. M. Edison a perfectionné ce système en disposant la poudre de graphite par couches, ce qui lui a permis d'accroître des variations plus grandes de conductibilité. Dans son appareil, le disque d'ivoire de notre Num exhibits de graphite et, enfin, d'un second disque d'ivoire. Cet ensemble est fermé par une plaque métallique commandée par une vis tangentielle dont l'index, en se déplaçant sur un cadran, indique le degré de la pression exercée sur le pile de disques semi-conducteurs. Dans ces conditions l'on peut faire varier la résistance du circuit de 500 à 4,000 ohms.

(*Chicago (Illinois).*)

A MESSIEURS LE COMTE DU MONCEL

Mon cher monsieur

Dans un des derniers numéros de la *Lumière électrique*, un article sur la mesure de l'intensité lumineuse m'a particulièrement intéressé. Le fait est qu'il n'existe point d'unité de mesure universelle, et c'est un défaut qui semble être resté inaperçu au milieu des utiles inventions de notre siècle.

Voulez-vous me permettre de proposer une unité par l'intermédiaire de votre estimable journal.

Puisqu'il est possible de mesurer avec une précision absolue la quantité d'un courant électrique, on pourrait-on pas utiliser ce courant pour produire une unité d'intensité lumineuse à l'aide de l'incandescence d'un fil de platine ayant un diamètre et une longueur déterminés, et traversé par une quantité connue d'électricité, étendons qui sont à la disposition de tout le monde scientifique. De cette manière nous pourrions obtenir un étalon, un véritable type permettant de déterminer l'intensité d'une lumière à l'aide de l'excellent et simple photomètre de M. Dove.

Je demeure, monsieur, cordialement à vous.

[11101].—Telephone Transmitter and the Induction Coil in Telephone Circuit.—"*J. H.*" will refer to the following pages, 92, 136, and 186 of the current vol. of the *M. E.*, he will find the information he asks for. His 30s. 24 and and 36 cotton-covered wire will answer for the induction-coil. Should he find any difficulty in making the vibrating break for working the coil, he will find a description of one, and the following simple device will be found to work well and quiet:—File a number of nicks along the edge of the brass staple S (see page 92), which supports the pendant piece P, so that it may somewhat resemble a fine saw (this roughing may be dispensed with, though I prefer it). Then take one of the ordinary watch-springs, better still, insert one end of an additional wire in one of the binding-posts on the stand B, and with a small piece of platinum file saw-like back. This will cause a rapid interruption in the battery current, and will produce almost as much effect on the telephone as the automatic interrupter; besides, it will sound the "call" when the battery is too weak to work the latter. Care, however, must be taken that the platinum-tipped spring does not touch the primary wire of the coil. This can be easily effected by inserting the additional wire first in one binding-post and then in the other, if the "call" cannot be got the first time. The carbons should be apart when the "call" is made; otherwise it will be weak. I was a good deal surprised at the reply to "J. H." sent by Mr. Lancaster, on the induction coil in the Gower-Bell circuit. My experience is just the reverse of that gentleman's, as the following will show experiments. If there be no alternatives, as he asserts, from using the induction coil with a carbon transmitter, why, may I ask, do Edison, Blake, Berliner, Crossley, Gower, and others make use of it in their carbon transmitters? Simply because they find it a real advantage; for one coil with an ordinary cell will do the work of ten or twenty without it on a long or badly-insulated line.—JOHN C. FRASER.

MT. LAN, OHIO, SATURDAY, JULY 9, 1881

Editorial Sentiments of the Telephone.

Mr. W. H. Ash, writing from Pensacola, in a recent note to the editor of the *Electrician*, says: "There are two cables landing here, one from Vigo and the other from Lisbon, both of which were, unfortunately for us, broken at the same time, the former in Vigo Bay, the other about 720 miles from here. Generally one or the other is always occupied, so that any experiments of this description are not possible, but being both idle, as well as our land line, I joined the two cables together here through a telephone. The other two ends being so far away I was curious to know what I should hear, and was very much surprised to hear Morse signals. After listening some time I found it was on the direct cable of the new French Atlantic Company, their line running from Pensacola to Brest (the cable lands about three-quarters of a mile from here), and their land line going to Pensacola by a different route from this company's. So that with no earth connection here, and none on the line except at Pensacola and Brest, I could read the signals distinctly. No doubt it was by the induced current, but that it can be perceived at such a distance may suggest to some ardent inventor uses for this very delicate instrument."

ELECTRICIAN, MAY 28, 1881.

3325. IMPROVEMENTS IN TELEPHONIC APPARATUS AND IN THE METHOD OF AND THE APPARATUS FOR TELEGRAPHING ARTICULATE AND OTHER SOUNDS, *W. Mc-cann-Brown.—Dated* 25th *September*, 1880.—6 *Communication from A. Graham Bell* (1 *to* 4*d.*

Fig. 1 shows the inventor's transmitting and receiving phelgmonic apparatus for the production of a musical sound. A rep four arm steel rod C is on a plane mirror, A, into a less, B, which brings it to a state of rest. The prongs of the rep-d at a certain point, is indicated by a perforated disc, C (see Fig. 2). As C is rotated the reps pass intermittingly through the holes in B, after which they are projected on to the less B', where they are again brought parallel, and thrown pass to the receiver E, a

thin disc of india rubber, F, in case G. This disc will be affected by the intermittent beams falling on it so as to produce sound-waves, which are transmitted to the ear of the listener by a flexible tube, I. The receiving instrument, shown at a less, I, is similarly used to concentrate the rays on F. By varying the speed of C the rapidity of interruption of the beams is equally varied, and consequently the pitch of the sound. In this form the motion which causes the interruptions is continuously in the same direction.

3° Quatrième différente des points de résistance de la couche liquide;

4° Quantité différente des points de rapprochement d'un pôle vers l'autre.

Mais il est évident que ce ne sont que quatre côtés du même fait, et ce fait est le *mouvement d'une des électrodes microphoniques*.

Il ne nous reste plus à examiner que la dernière catégorie

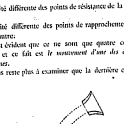

Fig. 1.

des microphones. Dans tous ceux qui sont connus jusqu'ici, la direction du courant pendant l'action de l'appareil reste la même; mais il est possible de la faire changer et d'introduire de cette manière une différence de plus dans les phases de sa fonction. Les fig. 2 et 3 représentent les deux positions extrêmes exagérées pour mieux montrer le changement; on voit la direction du courant qui arrive de la pile par deux

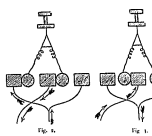

Fig. 2. Fig. 3.

fils très-fins, pour ne pas gêner les vibrations simultanées de deux morceaux réunis (sans contact électrique). En réalité, les deux boules vibrantes ne sont jamais isolées complétement d'aucun des charbons; mais il y a toujours une prépondérance d'un côté ou de l'autre. Ce microphone donne d'excellents résultats, mais sa construction est un peu difficile. Du reste, je le rends plus sensible à l'influence des mots prononcés, en ajoutant les deux morceaux sur une membrane d'une façon un peu plus compliquée.

Dans cette dernière catégorie, c'est donc aussi les points de contact qui changent et non pas seulement leur nombre.

En résumé, nous reconnaissons dans toutes les formes des microphones possibles :

1° Un mouvement mécanique des parties;

2° *Un changement dans les points de conductibilité*;

3° Un changement de résistance.

Et ces trois phénomènes essentiels, résultent l'un de l'autre. Je dis : « points de conductibilité » et non « de contact » parce que cette première expression embrasse à la fois les points de contact et la route traversée par le courant dans l'une ou dans l'autre direction. Nous voilà donc parvenus à une formule générale. Abordons maintenant les questions spéciales, et, avant tout, celle de la prétendue *amplification des sons* par le microphone.

Il est facile de se convaincre qu'elle n'existe point. *Tous les sons, consonnes ou voyelles sont toujours affaiblis par le microphone.*

Mais le microphone n'est pas seulement un appareil qui transmet électriquement les *sons*, il est aussi, et d'une manière plus particulière encore, l'appareil qui *transforme les ébranlements mécaniques en sons*, et ceux-ci peuvent être *amplifiés* dans cette transformation.

Exemples : Le tic-tac d'une montre de poche, posée sur la même planche que le microphone, quoique à une distance de 6 à 7 mètres, peut être entendu distinctement. Si cette montre est posée sur la planchette même du microphone, le son peut être entendu dans toute une chambre, parce qu'il agit, non comme *bruit*, mais comme *ébranlement mécanique*. Or cette même montre devient incapable d'influencer le microphone lorsqu'on la tient en l'air à une distance de quelques millimètres de celui-ci, parce qu'alors elle n'agit que par son *bruit*. En revanche, un faible souffle d'air, qui n'occasionne presque aucun bruit, fait l'effet d'un courant d'air, etc.

L'affaiblissement des sons articulés est d'autant plus marqué qu'ils sont plus intenses; de sorte que les sons les plus faibles éprouvent le moindre affaiblissement. Les sons musicaux simples, accompagnés d'un ébranlement mécanique relativement fort (par exemple d'un courant d'air sortant de la bouche quand on chante ou que l'on sifflé), *peuvent être un peu amplifiés* par un microphone à interruptions complètes, mais cette amplification n'a lieu que quand il s'agit de sons *faibles*.

Les ébranlements mécaniques, quoique non accompagnés de sons, *sont toujours transformés en sons*, et ceux-ci *augmentent en intensité à mesure que leur amplitude tend à interrompre le courant*. Cette interruption accomplie, l'augmentation cesse de se manifester. Un courant d'air n'agira pas plus fortement qu'un faible souffle, dès que celui-ci est assez fort pour provoquer une rupture momentanée mais complète du courant. Il y a deux limites entre lesquelles sont comprises toutes les lois des phénomènes microphoniques : la limite inférieure, où il y a naissance d'ébranlement mécanique et où le changement de contact est à peine réalisé, et la limite supérieure, où l'ébranlement interrompt le courant, indépendamment de l'énergie de cet ébranlement. Au-delà, il n'y a plus d'amplification, ni même d'articulation; mais entre ces limites, *l'intensité des sons est directement proportionnelle à l'énergie des ébranlements mécaniques qui accompagnent les ondes sonores*. Et comme les vibrations d'une ou de plusieurs parties du microphone déterminent une augmentation ou une diminution dans le nombre des points de bonne ou de mauvaise conductibilité, on en conclut que :

L'intensité des sons est directement proportionnelle à la grandeur des changements différentiels dans la résistance du microphone.

Pour que la transmission des sons articulés soit possible, il faut nécessairement que *le nombre des points de contact, les différences dans ce nombre, pendant l'action de l'appareil, et les changements de résistance qui en résultent, soient plus grandes*, C'est ce qu'on obtient dans la seconde catégorie de microphones, en réunissant de petites surfaces ne présentant qu'un seul point de contact, ou en employant des corps médiocrement conducteurs. Alors l'interruption du courant n'est que particielle, il devient modulateur, suivant l'expression de M. Hell, et plus il y a de marge dans cette interruption ou cette reconstitution partielle, plus le microphone est parfait.

Dr Julius Ochorowicz.

Untitled.

Sequential Telegraphicon

With a single telephone-hole, as in the right ear, the transmitted voice appears to come from a distance to the right; while with a telephone held to the left ear, it seems to arrive from the left of the listener.

With a telephone to each ear, if one ear be less sensitive than the other, or if the telephone be held further from that ear, the voice apparently shifts to the side of the other ear; and if both ears hear alike and both instruments are equally near their respective ears, the voice apparently proceeds from in front of the observer.

Nature 9 June 15. 1871.

Telephones for Long Circuits.—It has been found that wires, when employed for a telephonic circuit, are much more susceptible to disturbing causes than when employed for transmitting telegraphic signals. It has been observed that the slightest friction, such as will inevitably occur from the ordinary mode of joining telegraph wires, the closing of a pressure screw anywhere in the circuit, the slightest blow upon the wire, vibration from wind, the ordinary modes of supporting the wire, which produce no perceptible effect on the transmission of telegraph signals, are great hindrances to the transmission of voice vibrations, and thus confine the telephone to comparatively short circuits. It is thought if these hindrances could be avoided, the telephone circuit might be continued to as great a length as the telegraph—even across the ocean. Experiments are now in progress to determine all the facts connected with this matter. These experiments will involve the character, in quality and size, of the wire to be used, the best form of support, and a substitution of soldering the ends together, instead of the usual mode of joining. There is much reason for the belief that the telephone may ultimately as fully supersede the telegraph for long, as it already has for short distances.

ELECTRICITY & TELEGRAPHY

June 9 1876

Trial of Telephone.—Edison's telephone (so it is said) been successfully used over a line of 2000 miles in length. A meeting party in Delaware were thus enabled to converse with perfect distinctness with their friends in Pennsylvania, via Chicago and the Western Union Telegraph Company's line.

A Novel Use of the Telephone.—Inventor and Captain Green, of the United States Ordnance Department, the accurate determination of the time of flight of small-arm projectiles has been practically impossible at long ranges, owing to our inability to see them strike, even when firing over water. The discovery of the telephone has opened up to us a simple as well as a novel means of obtaining the time desired, and has also afforded us the means of verifying the formulæ by which three times were formerly obtained. In these experiments, two telephones precisely alike were connected (a form of Edison's carbon telephone) with a watch. One was placed within a few feet of the gun, and left open, so as to transmit the sound of the discharge. The other was in the shelter-proof, which was about 30 feet in front of the gun, and the target. A stop watch, beating fourths of a second, was used in connection with it. The telephone being at the gun, the instant the sound of the discharge was received at the target the watch was stopped. A mean of a large number of observations, which rarely differed more than a quarter to half of a second from each other, gave the time of flight. Of course there is a slight delay in starting the watch, but this is neutralized by a similar one in stopping it. The time given may, therefore, be accepted as strictly correct. It is worthy of notice that the time varies on different days, being shortened by a rear and lengthened by a head wind. The velocity of sound may be readily obtained with the telephone in the same manner. The time for the sound of the discharge passing through the air was always shown by the watch, but as it was not desirable for my purpose to stop the watch until the bullet reached the target, these times were not taken.

10

HUNNING'S MICRO-TELEPHONE TRANSMITTER.*

In its crude form the Hunning's Patent Micro-telephone Transmitter was in existence about three years ago, and has subsequently passed through a long series of modifications. Its present and most approved form was designed for the patentee by Mr. Cox-Walker, of York, to embody the various improvements suggested by experience. Its outward appearance is similar to that of the ordinary Bell telephone, but the resemblance stops there. The usual mouthpiece is covered on the under side of the opening by a piece of nickel-plated brass wire gauze, which forms a protection to a thin sheet of platinum foil. This foil acts the part of a vibrating diaphragm, and is in immediate contact with a very thin layer of granulated coke, which fills a small cavity provided with a brass plate at the bottom. The platinum foil is connected to one terminal through the brass ring, and the brass plate is connected to the other terminal. The terminal wires are then passed through the hole down the centre of the handle; the latter is screwed on to the central part, and the instrument is complete. In connecting it up for use, a receiving telephone (which may be Bell's or other similar instrument) is required at each end of the line in addition to the micro-telephone transmitter, and also a battery of Leclanché or other cells. The function of the transmitter is, by the aid of the battery current, so to increase the sound given out by the receiving telephone as to make these instruments a practical success, and also to overcome by its power the effects of induction from neighbouring wires, this latter having hitherto prevented the use of telephones on wires in the neighbourhood of others along which strong voltaic currents may be passing. The success of Hunning's Micro-telephone in this respect has been undoubted, and its clear articulation and power surprise all who hear it. The loose granulated coke between the two metallic plates is the secret of this success. When the platinum foil is spoken through at the mouthpiece, the aerial waves cause more or less of its under surface to come into contact with the grains of coke, at the same time causing those particles to press more closely upon each other, thus decreasing the amount of the resistance they offer to the passage of the voltaic current through them by bringing more points into contact with each other, this action taking place in a greater or less degree in accordance with the amplitude of the vibrations of the platinum foil acting under the influence of the sonorous waves. The control which this movement of foil and coke grains exercises over the passing current is most perfect and wonderful, and it renders the use of an induction coil, which is found to be so great a necessity with all other forms of telephone transmitters—Edison's, Crossley's, and Blake's, to wit—quite unnecessary; and by the use of a special form of receiver, which is now engaging the attention of Messrs. Hunning and Cox-Walker, the effects of induction are hoped to be entirely eliminated, the experiments hitherto made by them in this direction giving promise of ultimate success. An automatic switch board, with call bell and ringing key, completes the outfit for each end of a line for telephonic purposes. The instruments were successfully tried a few weeks ago between York and Darlington, a distance of about 45 miles, the wire used for the purpose of this test trial being one of about 20 of the ordinary telegraph wires which stretch from pole to pole along the side of the railway. The effects of induction were at times most powerful, but they did not prevent the easy and successful carrying on of conversation or the transmission of ordinary railway cypher messages between the two stations.

* Abstract of Proceedings of the Cleveland Institution of Engineers.

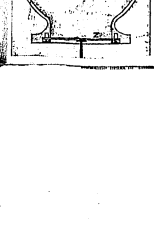
11

After all the wranglings and litigation between Bell and Gray as to the priority of the invention of the magneto-telephone it now transpires, on the authority of the United States Government, that neither Bell nor Gray were the inventors of the first magneto-telephone on record. According to the wording of the Patent Office the first claim filed for a patent on a magneto-telephone was by T. A. Edison. Why this fact, involving $1,000,000, has not before been brought to light is an interesting bit of history, and may serve as an index to the meanderings of genius and a fair illustration of the workings of the Patent Office system of Uncle Sam. The original specification was in a locked receptacle, in like fashion Edison, Bell and Gray were experimenting with telephones at the same time, and the latter three inventors, however, gave a public exhibition of their investigations until August, 1876, when Bell patented and exhibited his first telephone.

In December of the same year Edison established in Newark, N. J., an instrument for the manufacture of needles daily, and on the 18th of January, 1877, he filed a caveat in Washington his claim for a patent under the name of an acoustic telegraph, which was subsequently changed to that of telephone, reading as follows: Gray, Gray and Bell, by a singular coincidence, both on the 14th of February, the same day for patents on telephones which their last inventors, and three were the only telephones on record up to that time.

Mr. Edison at that time was in the service of the Western Union Telegraph Company, and as soon his claim to Messrs. Porter, Lowrey and Storrs, attorneys in the Western Union Building, New York, a reply was received from that the papers, as already stated, had neglected to return to Mr. Edison the official acknowledgment of the receipt of the papers from the Patent Office.

The inventions at that time, like the phonograph of Edison, had no commercial value, because it was available for sending messages only to short distances, and therefore of no quality for transmitting telegraphic currents, was at the best, imperfect. The commercial value, when discovered, as it subsequently was, by the lack of having filed his claim for his original magneto-telephone, and the neglect of Edison to look after his mind entirely, and did not examine into again until about three weeks ago, when Mr. Edison, the regular attorney for Edison in Washington, returned from a month's vacation of sojourn with his former partners, Messrs. Lowrey's lawyer by Messrs. Porter, Lowrey and Storrs. Among those papers was the discovery of the original claim filed by Edison for a magneto-telephone, the original telephone. The simplicity of its construction may be seen from the following cut:

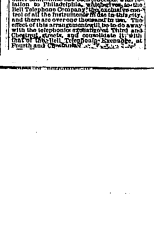


R, receiver; T, diaphragm; C, coil; M, magnet; A, line wire.

The specification referred to in the above cut (filed and which for unknown reasons did not reach the plaintiff in the suit) is in part as follows: "The object of my invention is to transmit telegraphic messages and other sounds to a distance by means of electricity, and consists in the employment of a diaphragm, preferably of thin sheet iron, which is caused to vibrate before the pole of a magnet, around which is a coil of fine wire, in such manner that the vibrations of the diaphragm cause undulations in the current of electricity passing through the coil, which undulations are transmitted to a similar instrument at the receiving station, and cause the diaphragm of the latter to vibrate in unison with that at the transmitting station, and thereby reproduce the sounds which are uttered before the transmitting diaphragm. I am aware that it is not new to transmit telegraphic messages and other sounds by means of electricity, and do not claim such, broadly; but I am not aware that any one has previously succeeded in transmitting such sounds by means of undulations of the current produced by the vibrations of a diaphragm in the manner above described, and I therefore claim the same."

Mr. Edison at that time was in the service of the Western Union Telegraph Company, and as soon his claim to Messrs. Porter, Lowrey and Storrs, attorneys in the Western Union Building, New York, a reply was received from that the papers, as already stated, had neglected to return to Mr. Edison the official acknowledgment of the receipt of the papers from the Patent Office.

The inventions at that time, like the phonograph of Edison, had no commercial value, because it was available for sending messages only to short distances, and therefore of no quality for transmitting telegraphic currents, was at the best, imperfect. The commercial value, when discovered, as it subsequently was, by the lack of having filed his claim for his original magneto-telephone, and the neglect of Edison to look after his mind entirely, and did not examine into again until about three weeks ago, when Mr. Edison, the regular attorney for Edison in Washington, returned from a month's vacation of sojourn with his former partners, Messrs. Lowrey's lawyer by Messrs. Porter, Lowrey and Storrs. Among those papers was the discovery of the original claim filed by Edison for a magneto-telephone, the original telephone. The simplicity of its construction may be seen from the following cut:



After all the wranglings and litigation between Bell and Gray as to the priority of the invention of the magneto-telephone it now transpires, on the authority of the United States Government, that neither Bell nor Gray were the inventors of the first magneto-telephone on record. According to the wording of the Patent Office the first claim filed for a patent on a magneto-telephone was by T. A. Edison. Why this fact, involving $1,000,000, has not before been brought to light is an interesting bit of history, and may serve as an index to the meanderings of genius and a fair illustration of the workings of the Patent Office system of Uncle Sam. The original specification was in a locked receptacle, in like fashion Edison, Bell and Gray were experimenting with telephones at the same time, and the latter three inventors, however, gave a public exhibition of their investigations until August, 1876, when Bell patented and exhibited his first telephone.

In December of the same year Edison established in Newark, N. J., an instrument for the manufacture of needles daily, and on the 18th of January, 1877, he filed a caveat in Washington his claim for a patent under the name of an acoustic telegraph, which was subsequently changed to that of telephone, reading as follows: Gray, Gray and Bell, by a singular coincidence, both on the 14th of February, the same day for patents on telephones which their last inventors, and three were the only telephones on record up to that time.

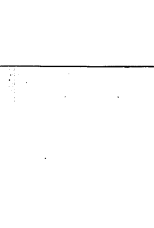
Lowrey's lawyer by Messrs. Porter, Lowrey and Storrs. Among those papers was the discovery of the original claim filed by Edison for a magneto-telephone, the original telephone. The simplicity of its construction may be seen from the following cut:



THE ATTORNEY-GENERAL *v.* THE TELEPHONE COMPANY (LIMITED).

(Before the Lord Chief Baron and Justice Lopes.)

On February 8th, in this case, Mr. Macrory, on behalf of the defendants, asked their lordships for liberty, on or before Wednesday, February 11th, to file affidavits in answer to those filed by the Attorney-General. There was an undertaking given that the affidavits should be filed by February 3rd. Certain negotiations were entered into which only terminated a few days ago, and pending these negotiations the defendants did not proceed with the affidavits. The negotiations had now been broken off, and the defendants asked their lordships for further time in consequence.

The Lord Chief Baron: I would merely suggest, Mr. Attorney, that, if it does not interfere with your other engagements, a case of such importance, affecting public and private rights, should be heard before us once and for all.

The Attorney-General: I am quite ready that such a course should be adopted, but I am anxious to protect myself against any accusation that I had been guilty of delay in the matter.

The Lord Chief Baron: I am sure no such accusation will be made against you, Mr. Attorney-General. You have the power to call upon us at any time to hear the case, and we will then appoint a day for it to be heard before three judges.

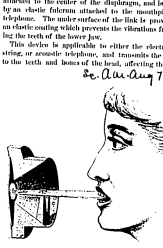
The Attorney-General: These remarks will also, I apprehend, apply to the case of the Edison Telephone Company, which will stand over until all affidavits have been filed and the evidence is completed.

DENTAL ATTACHMENT FOR TELEPHONES.

The engraving shows a device to be attached to an ordinary receiving telephone for transmitting the vibrations of the diaphragm to the teeth, to enable deaf persons to hear conversation, music, etc.

The device may be readily detached so that the telephone may be used in the usual way. A link of rigid sound conducting substance, such as wood or hard rubber, is connected with the center of the diaphragm, or with a disk attached to the center of the diaphragm, and is supported by an elastic fulcrum attached to the mouthpiece of the telephone. The under surface of the link is provided with an elastic coating which prevents the vibrations from affecting the teeth of the lower jaw.

This device is applicable to either the electric, or the string, or acoustic telephone, and transmits the vibrations to the teeth and bones of the head, affecting the auditory



DENTAL ATTACHMENT FOR TELEPHONES.

nerves, and enabling persons having defective ears to hear. This device was lately patented by Mr. H. G. Pinke, of Springfield, Mass.

Canned Salmon by the Cargo.

The first cargo of canned salmon of this year's catch, from the Columbia River, was lately cleared from Portland, Oregon, for Liverpool, England. It comprised 50,556 cases, each containing four dozen one pound cans, or their equivalent. The gross weight was over 1,400 tons. Two other ships were soon to follow, both taking nearly full cargoes. Large consignments have also been received at San Francisco, for reshipment to England, Australia, and New York. The steamer Oregon, from Portland, June 25, brought 22,556 cases, the largest invoice of the season, if not the largest single shipment ever made to San Francisco from the Columbia River.

AMERICAN MACHINES

Telegraph and Telephone Charges.

Alliance—

To any unprejudiced person who will closely this question, it must appear plain that the telegraph and telephone monopolies are standing, not only in their own light, but in that of the public. The telegraph companies started out with the notion years ago, that high charges and a small consistency were all that telegraphy had to expect, either then or in the future, and every absorption by them of a weaker rival has apparently fixed this idea more and more firmly in their minds. Acting upon this view, they have whittled out elaborate tables of rates, adding a few cents for every few miles of distance, here, there, and everywhere, as industriously as if transmitting a message 175 miles by wire really cost them a few cents more than sending one 50 miles. As a result, their tables of rates are as complicated as a war map of Afghanistan, and nobody thinks of taking the trouble to go to a telegraph counter, or of inquiring the rate (always considered a high-priced luxury) and sending a dispatch, unless under the spur of absolute necessity. The idea that telegraph blanks could be sold at a uniform price like ferry tickets, and that messages could be received and transmitted profitably to any part of the United States (east of the Missouri River) at the cost of the blank, say, 25 cents each, seems never to have entered the minds of the telegraph owners. If everybody knew exactly what a telegraph message would cost to any point, and nobody considered the rate exorbitant, every other man in the country would carry blanks around in his pocket ready for use, loan or sale, as men now carry postage stamps.

Let such a plan be adopted, and it is not too much to say, that where now one person uses telegraph facilities once a year, ten would use them daily and habitually. But the managers of this great modern invention are, strangely enough, fogyish, and afraid to try any broad gauge experiments in the way of either enriching themselves or benefiting the world at large.

The public should not lose sight of the fact, nor allow the telegraph monopolists to lose sight of it, that recent improvements in methods, actual or possible, have so cheapened telegraphy (notably the introduction of the quadruplex system, and the substitution of dynamo-machines in all the larger offices for the old plan of generating electricity by battery), that what a few years ago might have been considered an uncertain experiment, is now easily possible. The companies themselves are in no danger of forgetting that nearly all of the thousands of small offices at railroad stations throughout the country are run with little or no expense to themselves, as the operators are paid and the wires largely maintained by the railroad companies.

And so with the telephone. Its managers started out with too much capital than would suffice to run a wholesale grocery business, and think themselves rich because this capital has appreciated ten times in value. In New York they charge $90 per annum for the use of an improvement which could readily be afforded at $2 per month. As a result, one firm in fifty, and about one family in five hundred use it. The privilege of talking through the telephone should be as cheap and as universal as the use of coal gas or Croton water. And so it is elsewhere—like city, like country. From present appearances, the telephone companies bid fair in be decades of years in introducing an invention, which but for the exorbitant rates at which it is offered, would be eagerly adopted by the whole people within a few months, on account of its convenience and intrinsic merit.

Long Distance Telephoning.

To the Editor of the Scientific American:

Noticing an article in your issue of January 17, 1880, entitled "Long Distance Telephoning," I would like to say that nearly six months ago, in connection with the Western Union Managers at Marlor, Fort Wayne, Ind., and Defiance, Ohio, I talked with . much ease and clearness as ordinary conversation is now carried on in this city and suburbs by the instruments mentioned in your article, the distance being 160 miles; after which Toledo, Ohio, was put in the circuit, making in all over 300 es. The lines used were those of the Western Union Telegraph Company, and as such subject to many conditions as are likely to be met with in nearly any part of the country. The instruments were the Edison carbon transmitter and the Phelps pony crown telephone as receiver, the same as now provided by the Gold and Stock Telegraph Company, of this city, no special adjustment or preparation being made. The future of long distance telephoning is now resting at our doors.

LONG-LINES.

New York, January 16, 1880.

A Novel Extension of the Use of the Telephone

is reported from London. It consists in making the loud-speaking telephone of Mr. Edison—which embodies the principles of the electro-motograph—automatic by employing his small electric motor to turn the chalk cylinder. *Times* newspaper offices, and that a large number more are in preparation for the same establishment. The utility of this arrangement consists in the fact that the reporters of the paper, instead of dictating their short-hand notes to copyists, and transcribing the long-hand copy to the printer, simply read them directly to the telephone, thus saving the time of copying and carrying the report. The operator sitting at a type-setting machine in the printing-office, sets the type as one would play on the piano, as the words are transmitted to the automatic telephone. The saving of time on the compositor's account, as he has no copy to decipher, and other noteworthy utterances in the course of recent date makes the text of an enthusiastic sermon on the future of electricity, in which by the use of automatic and autographic telegraphy. "The indications are, that [illegible] with stenographic type-writing operating in conjunction you-must be almost instantly transmitted through long distances and at a fraction of the expense which such work now involves. Such inventions open up lines of progress too far-reaching for the boldest imagination to follow."

CONVENIENCE IN TELEPHONY.—A correspon[illegible] of the Manchester papers calls attention to a feature in telephonic [illegible] which has hitherto escaped public notice, but which, if [illegible] against, may give its way. The greatest advantage in this case [illegible] of the case of letter carrying, will probably prove to be [illegible] the adoption of a very enlightened monopoly. One firm, say, under the competitive system adopts one system, a second adopts a second system, a third a third, and so on. No. 1 wishes to converse with No. 2 or No. 3, but is unable to do so. Will the Gower give way to the Edison, or either to the Bell Telephone Company? Not so; they will get who have the power, and they will keep who can. The extract below is a portion of the letter we have referred to:—"It has been asserted several times that the 'induction' difficulty has been overcome; but if it is so, why don't we see the result of the discovery by all the wires being hung in some kind of order. As to the danger of falling wires, there is a light description of copper wire now being extensively used by Mr. Warburton, telegraphic engineer to the Lancashire and Yorkshire Railway Company, which is most suitable for street purposes, because if it falls it will not hurt anyone, besides, being so light it causes no strain on chimney stacks, and does not damage roofs when falling or being dragged along same, like the present heavy coarse iron wire. This is a very important matter to owners of property who allow wires to be attached to their places; but if the 'induction' difficulty has been overcome, the time has arrived for a wealthy corporation like Manchester to provide an iron pipe easily opened from the top, along the footways of all the chief streets, to contain all the telegraph and telephone wires. It might be made something like the water channels in Paris, and each company or owner of a 'set' of wires, if deemed necessary for extra protection, could cover them with metal, similar to a submarine cable, then all the unsightly overhead wires could be swept away. There is another matter of very great importance that should be taken up at once by the Chamber of Commerce, and that is the 'muddle' that will ensue owing to having two Telephonic 'Exchanges.' For instance, Mr. Smith, at his Ardwick Works, decides to have a connection with the 'Edison' Exchange, because on the other side of the town he has half-a-dozen firms he would frequently like to talk with; but when his wire is finished he finds half his friends have used the 'Lancashire' Exchange, a different building, and using a different instrument, so that Mr. Smith only gets half the value out of his venture. The companies should either amalgamate or choose separate towns, though the latter mode would only prove a temporary relief, as the time is not far distant when the merchants of one town will chat with those of another, notwithstanding the Government telegraphic monopoly of the present day."

THE TELEPHONE.

A Description of This Interesting Invention of Pittsburg Electricians.

Much interest has been excited in the recent invention of Messrs. Connolly Bros. & McTighe, the Pittsburg electricians and electricians, which was briefly mentioned in a Dispatch special yesterday. The claim made is the ability to transmit the physical wave force of light, electricity, similar to the transmission of sound by the telephone. It having been demonstrated that electricity is a creation of solar light, the principle bearing this invention is the transmission of electricity back again into light and, in the case of underground, the reproduction at the point of destination of the object submitted to the action of the solar or powerful electric rays at the point of transmission. It is claimed by Mr. McTighe, with whom our reporter conversed, that the principle involved in the new invention is sufficiently perfected for practical use it will be possible for one of the most interesting, or telephone to perform electric miracles, such as those the tongue of the person with the telephone to his ear, the practical utility of the invention will, however, be more thoroughly appreciated when it is known that by its means it will be possible to be able to transmit instantaneously from point to point, any written or printed document, picture, miniature, one entire city or a newspaper.

The reproduction of the image is the result of chemical changes which are now utilized in the science of photography and are perfectly familiar to every student of chemistry or of science and art. The inventors began their investigation of the subject several months ago, and have since been working with a firm attempts made at the development of the telephone. In order to be able to work undisturbed, they removed to the top of the Oakland, the Washington block of the above firm, took up the subject of photography as employed in connection with the telephone, and have made new plates and discoveries during the past few months which have electrified away at Washington, with proof of same, so that they are fully prepared to turn over the invention to the public, and will not be efforts be made to disturb the secret.

The comparative impracticability of the telephone for long distances at present lies in the fact that it requires a powerful battery to transmit the image. The telephone, like the telephone, requires but a single wire, is well transmitted, the image of any object however small, and the reproduction at the point where is magnified at the receiving point, before the reproduction in the required size.

The inventors have, in their experiments so far been able to reproduce, clearly and faithfully to a dark room at his residence, the image of persons at the other end of the line or in a room in another part of the house, and that with the telephone is yet in its infancy, of its ultimate perfection and utility there can be no doubt whatever.

SCOTTISH TELEPHONIC EXCHANGE.—The prospectus of this company contains the information that telephone exchanges are in general use in eighty-five of the principal towns of the United States. In Chicago, as has been previously stated in *The Electrician*, there are over three thousand members in communication. The first telephonic exchange in this country was started in July, 1879, at Manchester. It is also stated that the time required to put two members in communication does not exceed half a minute. It may be useful here to make a statement, and ask our readers if they can supply any corroboration to the story. A gentleman assures us that the string telephone was in use in Ceylon quite twenty-five years ago, and that it was to be seen in business houses.

THE GOVERNMENT AND THE TELEPHONE.—A correspondent has written to *The Times*, pointing out that in America the telephone exchanges help the telegraph companies by connecting up villages to their systems which would not be able to support a regular telegraph office.

—A patent has been applied for, by Mr. J. D. Husbands, as agent of Edison, for certain improvements in the telephone. It is proposed to connect friends' houses by wires. What a nice thing for the ladies!

—The telephone [illegible] between the American Union Telegraph Company [illegible]

LONG-DISTANCE TELEPHONING.—A recent trial of Bell's telephone between Dayton, Ohio, and Indianapolis, Indiana, proved that it is quite suitable for talking distances under 100 miles in the United States.

THE TELEPHONE IN WHEATSTONE'S BALANCE.—Herr Niemiller employs a telephone instead of a galvanometer in the bridge wire when measuring the resistance of liquids, with a gain in delicacy. An induction current is used, and it is found that when the galvanometer gives no deflection the telephone gives a distinct sound.

THE GOWER TELEPHONE.—As we mentioned in our last issue, the Gower Telephone Company are to use a microphonic transmitter for working their apparatus. The arrangement of this transmitter is shown by the fig.; it consists of 6 microphones formed of 6 carbon rods, the outer ends of the latter are set in carbon blocks fixed to metal plates, to which the connecting wires are attached, as shown; the 6 inner ends rest in a single carbon block on the centre of the arrangement. The whole is secured on a wooden board against which the sound waves impinge. The system in fact differs

but very slightly from Crossley's microphonic transmitter which was described in the number of the Journal for May 1st, 1879.

Danger of Lightning From Telephone Connections.

The Cantonal Government of Zurich, having been applied to by a telephone company for permission to fix the supports of insulators on the tops of certain public buildings, applied to Prof. Kleiner for an opinion. The following is a summary of the chief points in his report.

1. The danger of lightning in houses over which telephone wires are stretched is not increased, but lessened, if the total conductivity of a wire is approximately equal to that of a lightning conductor. This condition is not always fulfilled under existing arrangements. It may be lessened by very simple arrangements, such as the introduction of a special wire for the conduction of lightning wherever the number of wires of two millimeters in thickness running in the same direction is less than sixty. This should be insisted upon in all cases. Single connections running along the houses should be stronger than at present—at least as strong as telegraph wires.

2. As the properties of a telephone adapt for attracting and conducting lightning extend over far wider tracts than those of a lightning rod, a strict regulation of their make and condition is necessary.

The use of telephones should be suspended during thunderstorms.—*Neue Zurich Zeitung.*

Extreme Sensitiveness of the Telephone.

Mr. W. H. Ash, writing from Penzance, in a recent note to the editor of *The Electrician*, says: "There are two cables landing here, one from Vigo and the other from Lisbon, both of which were, unfortunately for us, broken at the same time, the former in Vigo Bay, the other about 750 miles from here. Generally one or the other is always occupied, as that any experiments of this description are not possible, but being both idle, as well as our land line, I joined the two cables together here through a telephone. The other two ends being so far away I was curious to know what I should hear, and was very much surprised to hear Morse signals. After listening some time I found it was on the direct cable of the new French Atlantic Company, their line running from Penzance to Brest (the cable lands about three-quarters of a mile from here), and their land line going to Penzance by a different route from this company's. So that with no earth connection here, and none on the other line except at Penzance and Brest, I could read the signals distinctly. No doubt it was by the induced current, but that it can be perceived at such a distance may suggest to some still further uses for this very delicate instrument."

JUVENILE LECTURES AT THE ROYAL INSTITUTION OF ARTS.

The first of two lectures, by Mr. W. H. Preece, M.A.C.E., adapted to a juvenile audience, was delivered by that gentleman on last Thursday evening at the Society of Arts, Johnstreet, Adelphi. The lecture was strongly crowded, the audience being composed for the most part of children and friends of members of the society, who listened very attentively to the interesting remarks of the lecturer, and frequently testified their pleasure by vociferous applause during lengthy pauses. The lecture was on "Recent Wonders of Sound," and, as promised, it was fully illustrated, explanatory diagrams being suspended from the wall of Hoyer's, Bell's, and Edison's telephones, Edison's phonograph, Mr. Hounsfield's phonoscope, and Crossley's telephonic transmitter, which, by the kindness of various firms, were made by the lecturer to demonstrate his remarks in a practical manner. In the various experiments carried out Mr. Preece was assisted by Messrs. Sivewright, Mr. Stroud, Mr. Leish, and Mr. Wilson. At the outset of the proceedings, Mr. Preece said he had nothing of a very novel character to bring before them, his object being, in fact, to introduce the mind of young people into that old fact that the advances in science had been chiefly attributable to the application of facts, which had become new facts to light. Doubtless they had all at one time or other made simple experiments in connection with the phenomena of sound, and he had done any practical reference or learn any lesson from it and now it was to exercise their memories as well as their hands and eyes, and to show them not only how to set their cases. Sound was recognised by the vibration of matter, air consisted of molecules, of which there were millions and millions in the room in which they were then assembled. He then showed how the molecules were set in motion, and how sound was produced, by sending a beat which he had previously filled with smoke, by forcing on a whistle, and by acting in similar manner on a jar of a few inches away from the leftmost. Every time he threw these molecules into vibration by speaking or making any noise the sensation called sound was produced. Referring to the speed at which sound travelled, he remarked that that was the reason why there were such things as echo, in which sound travelled at the rate of 1,100 feet per second in wood. The velocity of those molecules through the air was very interesting. It was very complicated to explain on account of the various ways by which they set in motion. Sometimes made by the compression of a column of air, by which they were affected by the motion of the molecules, a note or the noise from a pistol, separate qualities. First, the pitch of a note, or the noise from a pistol, was produced by the number of vibrations per second, by forcing on a whistle, and by acting in similar manner on a jar of a few inches away from the leftmost. Every time he threw these molecules into vibration by speaking or making any noise the sensation called sound was produced. Referring to the speed at which sound travelled, he remarked that that was the reason why there were such things as echo, in which sound travelled at the rate of 1,100 feet per second in wood. The velocity of those molecules through the air was very interesting. It was very complicated to explain on account of the various ways by which they set in motion. First, the pitch of a note was produced by the number of vibrations per second, by forcing on a whistle, and by acting in similar manner on a jar of a few inches away from the leftmost.

TELEPHONY.

The Postmaster-General has at length decided to grant licenses to different companies to establish and operate telephonic exchanges throughout the Kingdom. This license confers no special power to erect poles and wires on or under any public highway or private property. Licensees will have to make their own arrangements with the local authorities, and any persons whose property may be affected. Nor does the license confer authority to carry on telephonic business with any instrument which is an infringement of existing patent rights. This result will cause general public satisfaction, as there has been a growing feeling of late that the changes of the company now possessing exchanges are higher than is desirable. Competition will have the effect of reducing those rates. Already we hear of at least one opposition company about to appear, and doubtless others will in time follow. In connexion with this subject we notice that the disclaimer of the phonograph from the Edison telephone patent has been allowed by the Attorney-General.

LONG DISTANCE TELEPHONING.

In a recent Note we gave an account of the plan employed by M. Van Rysselberghe for suppressing induction on long telephone lines. The method has, we understand, been recently tried in England between Peterhead and Victoria Station on a mail-line wire, and found to give satisfactory results. The experiments were carried out by the engineer of the United Telephone Company, Mr. T. Fletcher. The arrangement consisted in putting electromagnets between the signalling key and the line on those telegraph wires running alongside the telephone wire. The ordinary Morse signals were thus "softened" in such a way as to prevent their induction on the telephone wire making a disturbing sound in the telephones. The telephones could also be connected to the wire carrying the Morse signals, so that a Morse and a telephonic message traversed it together. This was done by employing the electro-magnet as before, and inserting condensers between the telephones and the wire. The obvious drawback to this system of Mr. Van Rysselberghe is that the telegraphic and not the telephonic lines have to be manipulated. As in this country the telegraph lines are in the hands of the Government and the telephone lines in those of a private corporation, it necessitates a combined action which is unlikely to take place, more especially as the insertion of electro-magnets into the telegraph circuits is calculated to retard the speed of working of the lines. A better solution of the difficulty would be an arrangement which abolished the telephone itself from the effects of induction from without. While upon this subject we may advert to the recent report that the bombardment of Alexandria had been heard through the Abyssinian mountains, a distance of 1000 miles. This is obviously not correct, for the inductive retardation on so long a cable would undoubtedly obliterate the simultaneous currents necessary to produce the sound of the bombardment. The fact that speech was not transmitted is itself a proof of this. What was probably heard, if anything was heard at all from Alexandria, was the effect of the mechanical shock to the transmitter at Alexandria produced by the concussion of the guns. The recent telephonic trials of Mr. Van Rysselberghe over a cable many miles long, though attended with success do not prove much either, for 60 miles is but a short cable, and is comparable with a long land line. Though the telephone is heard through 60 miles of cable, 100 miles would probably absorb the sound, since the inductive retardation increases as the square of the length. Some time ago the telephone was tried successfully on a longer cable, namely, one of 75 miles, at Bongnes, but we have not heard of artificials speeds traversing 100 miles of cable.

une chambre frigorifique à la Vougre de Paris. Les hommes comptents ont eu effet le droit d'être employés concurremment aux machines actuellement connues, la production du froid par l'évaporation des liquides volatils est beaucoup plus économique que cette obtenue à l'aide de la compression de l'air qui nécessite une installation mécanique considérable. La Commission assistera par le poids de la Seine contient le centième. M. Th. Tellier démontre qu'elle a été obtenu en retenu, ce qui, assurément, est bel et bien réel.

LES COMMUNICATIONS TÉLÉPHONIQUES

AUX ÉTATS-UNIS

Si l'Amérique est le pays des réclames invraisemblables, elle est aussi par excellence le pays des applications pratiques. Alors qu'une se donne à peine en France de ce que peut être un service de communications téléphoniques, on compte actuellement dans le Nouveau Monde, 85 villes qui se servent journellement de ces installations. A Chicago il y a 2000 abonnés, 600 à Philadelphie, autant à Cincinnati, un nombre sans cesse croissant à New-York, et le chiffre de personnes abonnées aux Compagnies téléphoniques dans l'Amérique dépasse 70 000. A Paris, il ne s'est pas fondé moins de trois compagnies dans le but d'établir de communications téléphoniques à l'instar de l'Amérique; la première avec le téléphone Edison, la seconde avec le téléphone Bell et le transmetteur Blake, la troisième avec le téléphone Gower. Cette multiplicité de compagnies a rendu les futurs abonnés hésitants, et par suite fort réservés; il y a eu tentative de fondation d'une association nouvelle. Les installations téléphoniques ne sont encore qu'en voie d'organisation, et nous n'avons pas à en parler, du moins pour le moment. Chose à noter, car elle est rare : dans l'espèce, la concurrence fait l'application, et il en sera ainsi jusqu'à ce que, par des moyens que nous n'avons pas à examiner ici, on arrive à une entente que nous souhaitons bien vivement pour notre part, car la question présente un intérêt et un avenir immenses à tous les points de vue.

Transportons-nous à New-York par la pensée et voyons comment fonctionne le service du téléphone.

Si nous pénétrons au milieu de la grande salle du bureau central du *Merchant's Téléphone Exchange*, établi 198, Broadway, fig. 1, nous verrons une série de rectangles emplissés, occupés à établir les communications entre les abonnés. Là c'est un switchman correspondant avec un des abonnés qui a appelé (fig. 2); plus loin c'est un autre employé occupé à relever le signal d'avertissement (fig. 3). Dans la ville, chez l'abonné, est le *téléphone de bureau*, tel qu'on l'installe dans un grand nombre de maisons (fig. 4); ce modèle est très commode pour les affaires, car il permet de parler dans l'embouchure d'une plaque à gauche, d'écouter avec le téléphone, placé à droite pour l'appliquer à son oreille, et en même temps de prendre des notes sur le papier que la main restée libre.

Avant de suivre la série des opérations qui constituent un appel complet, examinons rapidement le système de téléphones employés dans le bureau de Broadway.

Ce système appartient à la classe des *téléphones à pile*, ce qui permet d'utiliser ces piles pour faire les appels chez les abonnés, à l'aide de sonneries ordinaires, sonneries représentées sur le poignet de la figure 4.

Transmetteur. — Le transmetteur est le téléphone à charbon d'Edison[1], fondé sur les variations de résistance électrique produites par les variations de pression qu'exerce la plaque frappée en parlant devant l'embouchure. Le circuit est fermé par la pile, — 2 éléments Leclanché — le transmetteur et une petite bobine de induction d'environ cinq pieds. Il constitue le circuit primaire de la bobine. La ligne et le récepteur de l'autre poste, sont reliés au fil secondaire de la bobine. Il doit donc être terminé est relié au récepteur du poste et à la terre. Il en résulte que les courants de ligne sont les courants *induits* par les variations d'intensité du courant qui traverse le fil primaire de la bobine. Cette disposition a pour effet de transformer en courants de tension les courants ondulatoires des trans-metteur, de les rendre moins sensibles aux variations de résistance de la ligne, de faciliter la transmission et de supprimer partie des communications, dont le maintenant pourrait causer des erreurs.

Récepteur. — Le récepteur est un téléphone Phelps, analogue au téléphone Bell, mais dont l'aimant est retourné en forme d'anneau, ce qui rend son maniement assez facile (fig. 4).

Dans la position de repos ou d'*attente*, le téléphone est pendu à son crochet, et par ce fait seul,

[1] Voy. *la Nature*, table des matières des années précédentes.

dans le sifflet A, *fixé à demeure fixe* sur le corps du téléphone, il transmet ses vibrations dans la chambre qui se trouve en dessous de la membrane vibrante. De la sorte on évite toute fausse manœuvre, on ne doit parler quaprès avoir reçu le coup de sifflet-avertisseur. Chacun doit agir ainsi. On écoute en portant un téléphone à chaque oreille.

La correspondance terminée, on dit sur repos, et les deux *fiches* mettent chacun la manette dans cette position, pour attendre un nouvel appel. Chaque poste, lors qu'il transmet, *peut sans en avertir*

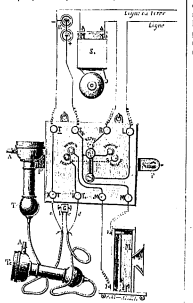

FIG. 1. — Poste téléphonique de M. Bourseul.

son correspondant, se servir du microphone transmetteur; il lui suffit de placer sa manette sur *microphone*, et, si lui-même veut entendre dans son propre téléphone, les sons qu'il transmet par son microphone, il lui suffit encore, sans aucun avis, de placer sa manette à cheval sur les deux goutfes, *téléphone microphone*

Les téléphones, au repos s'accrochent en PP. En résumé, ce poste est *simple*, sa manœuvre facile. L'*appel par sonnerie* est ainsi prolongé et aussi puissant qu'on le désire; la sonnerie d'appel peut être placée loin des téléphones dans des pièces de service; plusieurs sonneries peuvent être placées à différents endroits; toutes on isolement, à volonté, par le jeu de commutateurs bien connus, peuvent recevoir cet appel. Ce genre d'appel par sonnerie, doit donc être préféré à tout autre, à cause de sa simplicité.

Le téléphone employé dans le poste que nous venons de décrire et qui est dû à M. Bourseul, ne diffère des systèmes connus que par une complication spéciale de l'embouchure (*fig.* 2), et l'addition d'un *sifflet-signal* fixe. L'embouchure étant métallique; elle n'est plus soumise aux variations hygrométriques, qui, dans les téléphones à embouchure de bois, agissent constamment sur le serrage de la membrane M, et par suite, modifient le réglage et la sensibilité du téléphone. Ces vibrations ne se produisent plus avec l'embouchure métallique, elle reçoit la membrane M, laquelle est maintenue par une bague de laiton, par le *serrage* même de l'embouchure. Ce serrage de la membrane est ainsi très régulier sur toute sa circonférence. Un sifflet A, placé à demeure fixe sur le corps du téléphone, transmet ses vibrations dans la chambre qui se trouve en dessous de la membrane M. Chaque fois qu'on a fini de parler on avise son correspondant en sifflant en A.

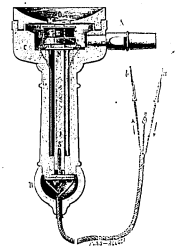

FIG. 2. — Téléphone employé dans le poste précédent.

Ce signal convient est très efficace, il s'entend bien et il évite les fausses manœuvres dans la correspondance téléphonique.

On voit que le téléphone se complète chaque jour par des dispositions ingénieuses qui en font un instrument tout à fait pratique.

PREACHING BY TELEPHONE.—*The New York Mercantile Journal* of the 24th ult. gives a report of a sermon preached by Mr. Beecher, with two transmitters under the pulpit, connected through the Central Office of the Bell Telephone Company with about fifty different places in and about the city. One of the places connected was in Elizabeth, New Jersey, some 15 miles distant, where a large party were assembled to witness the experiment. Here, it is said, the success was perfect. All the morning service, including the singing, the prayer, the reading of the Scriptures, and every part of the sermon, was heard as distinctly as at all the other places, worshipping in Plymouth Church, At Newark, and at some places in this city, the results were quite effective, but the sermon was not in every instance heard so distinctly as in Elizabeth. The trial was repeated in the evening and was just as successful as in the morning. The *Journal* describes this as the beginning of what may yet turn out a new era in church-going and concert-going.

Le téléphone vient de recevoir en Angleterre une application très-importante. Chacun connaît l'obligation de parler de son utilisation à la reproduction, dans le *Times*, des débats parlementaires de la Chambre des Communes et des Lords. Ces débats, comme on sait, ont lieu la nuit et se prolongent souvent jusqu'à une heure très-avancée de la nuit.

La composition, c'est-à-dire l'assemblage des caractères d'imprimerie qui forment un journal de l'importance du *Times*, n'est pas une petite affaire et l'on ne peut s'en rendre un compte à peu près exact que lorsqu'on a certaines connaissances de la matière. L'ouvrier typographe habile, posant les lettres à la main, ne peut, en général, en moyenne, dépasser 40 lignes par heure, ou un maximum de 50 lignes, pendant de courtes périodes de presse extrême.

Pour remédier à cet inconvénient, une machine a été substituée au travail manuel dans la composition du *Times* — depuis 1871, croyons-nous. Nous ne décrirons pas la machine; nous nous contenterons de dire qu'elle met elle-même les caractères en position, au moyen de touches que l'on frappe, comme les touches d'un piano. L'ouvrier suffisamment exercé peut composer en moyenne 100 lignes par heure, même quand il compose sur un manuscrit qu'il doit lire lui-même; cette rapidité peut être beaucoup plus grande et presque doublée, s'il est assisté d'un lecteur qui lui dicte la composition.

Par cette combinaison, on obtenu de remarquables facilités pour publier les manuscrits qui viennent très-tard, et, l'on donne à la composition presque jusqu'au moment où l'on met sous presse.

Mais avant tout, il faut avoir la copie, c'est-à-dire le manuscrit, et par conséquent, laisser aux personnes chargées de reproduire les débats parlementaires le temps de transcrire leurs notes sténographiées et de les envoyer au journal. Un temps précieux était perdu par ce fait. Pour y remédier, le *Times* a eu recours au téléphone, comme moyen de transmission, et a obtenu l'autorisation d'établir une communication, par un téléphone, entre la Chambre des Communes et son imprimerie.

Les notes prises par le *reporter* sont lues directement au téléphone, dans des galeries voisine du lieu des séances, et le compositeur, assis à sa machine, dans l'imprimerie, recueille les mots à l'autre extrémité de l'instrument. Des signaux très-simples indiquent qu'il est prêt à recevoir le message, qu'il l'a reçu, l'a compris, etc., ou bien que la transmission est incomplète et qu'il y a lieu de donner des explications.

Dans cet ordre d'idées, l'application téléphonique est encore à son début, et des modifications viendront bien certainement l'améliorer; cependant, les résultats obtenus sont très-appréciables et suffisent pour montrer ce que l'on doit en attendre.

Quelque avantage que présentent les moyens de publication rapide adoptés par le *Times*, il ne faut pas perdre de vue qu'ils ont l'inconvénient de ne pas permettre au reporter qui transmet un discours de vérifier l'exactitude du texte et d'y opérer les corrections même les plus nécessaires, qui ne peuvent manquer de se glisser dans une transmission aussi rapide.

THE AMPLITUDE OF TELEPHONIC VIBRATIONS.

The amplitude of the vibrations of a Bell receiving telephone have been ingeniously measured by M. G. Sabt. To the iron diaphragm of a Bell telephone he fixed a little disc of glass weighing 0.45 grammes, and in front of it placed a second, the first. The arrangement it will be seen resembles Finzee's plan for studying dilatations. When the telephone is spoken to direct, at a distance of 15.0, or 20 th., or when a current is sent through it from a good transmitter, such as Bottachio's, which requires no battery, the rings are seen to lose their distinctness, and disappear if the voice is raised a little. The rings, in fact, vibrate in correspondence with the diaphragm of the instrument, and it is easy to calculate from the displacement of the rings the amplitude of the telephonic vibrations. To estimate the displacement of the rings, a turning disc perforated with holes like a phonautograph, is placed before a receiver which is caused to emit a continuous note. For a certain speed of rotation the rings reappear with distinctness. If then, one blows through the disc so as to make it act like a syren, one demonstrates that the sound produced is in unison with that transmitted by the telephone. If it is lowered or raised slightly, the rings oscillate, at first gently, then with such rapidity that they become invisible. Whilst they oscillate their displacement can be estimated. In one experiment made by emitting in the transmitter the "A" of the diapason, or the vowel "a" with moderate intensity, the displacement was equal to the distance between two consecutive rings. This corresponds to an amplitude of the telephone plate of from two to three ten-thousandths of a millimetre. When the displacement is not equal to the distance between two rings, the brightness of the ring taking a point of the glass plate as zero, will give an estimate of the strength of current in the telephone.

RECENT ELECTRICITY.

At the suggestion of one of the proprietors of this journal

—Mr. A. E. Beach—a series of interesting experiments relating to the electrical transmission of sound has lately been commenced in this vicinity, which seems likely to lead to a variety of useful results. The introductory experiment the Scientific American editor and Mr. Beach's dwelling, in the upper part of this city, were connected by wires with the auditorium of Plymouth Church—Rev. Henry Ward Beecher's—in Brooklyn, N. Y., and three points were also telegraphically joined by the wires of the Bell Telephone Company and those of the Gold and Stock Company, the electrical circuit being thus enlarged and ramified in all directions, communicating with offices and dwellings in New York, Brooklyn, Jersey City, Newark, Orange, Elizabeth, Yonkers, and other adjacent places. One object of the experiment was to determine approximately through how many united circuits and lines the voice of a public speaker might be simultaneously transmitted.

At Plymouth Church, in Brooklyn, the wire passed under the floor to the platform or pulpit, where it connected with two of the well known Blake transmitters, arranged upon a shelf under the speaker's desk. The general arrangements for the experiments were under the charge of Mr. Frederick C. Beach, Ph.B., of the Scientific American office.

When it became known at the Bell telephone office in Brooklyn that experiments were to be tried, the interesting news soon spread to all of the other telephone offices, and the various operators not only called into the offices parties of their friends to enjoy the treat, but gave notice to numbers of private persons having communicating wires, who in turn invited friends to their dwellings. Thus at many points on the great ramification of connecting wires were groups of persons waiting, with telephones at their ears, to hear the words of the distinguished speaker. At one of the stations fifteen telephones were in this way connected, the instruments being joined by wires, just as a circle of people join hands in sharing an electrical shock.

The first experiment was made on Sunday, April 18, and was on the whole perhaps more successful than could have been expected. The telephone listeners stationed in Brooklyn, and nearest the church, were enabled to hear the service with much satisfaction; but those in New York, Yonkers, and Orange, N. J., only heard the music and portions of Mr. Beecher's sermon. It was concluded on the whole that there were too many telephones in circuit; and it was subsequently ascertained that the wire leading to the church had been surreptitiously tapped where it passed over a dwelling, a ground made on the tin roof, and a considerable number of telephones smuggled in.

On the following Sunday, April 25, another trial was had, precautions having been taken not to allow so many tapping liners or instruments in circuit. Special care was also taken by Mr. Adee, the adjuster of the Bell Telephone Company, to give the most perfect adjustment to the transmitting instruments at the church. The result was most successful and marvellous.

From the opening note of the organ prelude to the last word of the preacher's voice, at the close of the service, everything was delivered to the ears of the listening telephoners in the most perfect manner, the tones that came over the wires being so full, round, clear, and distinct, it almost seemed to the hearers in New York, Yonkers, and Elizabeth as if they were stationed within the church itself directly in front of the speaker.

The delivery of the music was equally perfect, every note of the organ and of the individuals of the choir being fully brought out. The majority of the listeners in this experiment were persons accustomed to the use of the telephone, and their unanimous verdict was that the results obtained far surpassed anything of the kind within their previous experience.

In consequence of the successful progress of these experiments, several new improvements have been suggested for trial, and there seems to be every probability that in a short time some new and very effective instruments will be in use, by which all who desire may carry the sounds of church services into their dwellings, and may also enjoy the best lectures, musical and other entertainments with the utmost satisfaction in their homes. Hereafter, in listening to the telephone, it has required effort and strain of the ear on the part of the listener. But this experiment shows that all sounds may be delivered in full and easy tones, readily heard, with all the natural characteristics, modulations, and lusciousness of the human voice.

We shall keep our readers informed of the further results accruing from this series of experiments. With the continued co-operation of the various electricians and managers of the lines it is believed that something of value to science may be adduced.

The progress and success of the experiments up to the present time have been greatly promoted by the active interest taken and assistance rendered by the gentlemen connected with the several telephone companies, to all of whom we return our sincere thanks. We are under especial obligations to Mr. C. P. Wiley, Superintendent of the Gold and Stock Company; to Mr. H. R. Butler, Secretary of the company; to Mr. T. G. Ellsworth, Electrical Manager of the company, through whom the experimental circuits were in the first instance arranged; to Mr. Henry W. Pope, Superintendent of the Bell Telephone Company; to Mr. E. T. Greenfield, Assistant Superintendent; to Mr. C. N. Chinnock, Electrician of the company; to Mr. H. M. Adee, Adjuster of the company; to Mr Robert Brown, Superintendent of Construction; Mr. Grinstead, of the Orange office; Mr. Alfred Hanford, manager of the Brooklyn office, Mr. Charles Walton, manager of the Nassau-street office, N. Y. Mr. R. W. Macgowan; to Col. Wm. H. Paine, C.E., and to C. C. Martin, C. E., Assistant Engineer of the great Suspension Bridge between New York and Brooklyn, for permission to lay a temporary experimental wire across the foot bridge.

Engineering Dec 4. 1883.

The *Electrician* (New York) for October contributes to the Bell owner Hels controversy a letter from Mr. H. C. Beck, enclosing one from Mr. H. F. Peter, a teacher of music in the village of Friedrichsdorf, which was for many years the home of Philipp Reis, and which contains the Garnier Institute, where he was interested in physics. Herr Peter states that he was present at Reis's experiments, and can testify that precisely speech was actually reproduced by the telephone. He says that many members of the "Physikalischer Verein," of Frankfort-on-the-Main, were also present.

A trial of the system of signalling by electricity was recently made on a portion of the New York elevated railway, which has been equipped with the apparatus for keeping trains 300 ft. distant from each other. Each locomotive carries a small chrome battery, wound for electromotive force, and the current is continually flowing, making a closed electric circuit as a mode of operation. Two of these were placed upon the line, one soon after one of them came within 300 ft. of the other; it started automatically a signal, which caused a bell to ring in the cab of the other locomotive; and it continued ringing until the first engine had moved on out of the 300 ft. circuit. No further details or explanations are given.

LE MICROPHONE

APPLIQUÉ A LA MÉDECINE

22 Mars 1879

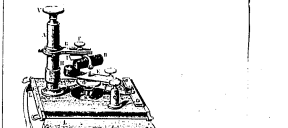
On a souvent parlé de l'importance que le microphone pourrait offrir au point de vue médical; il ne nous paraît pas nécessaire d'entrer dans des développements à ce sujet; nous nous bornerons à faire connaître un instrument récemment construit, et qui nous paraît de nature à être recommandé.

Dans une dernière séance de la *Société de biologie* M. le docteur Bondet, de Paris, a donné la description d'un microphone très sensible, monté sur un double ressort de sphygmographe, et qui lui a servi à faire des recherches intéressantes dans le service de M. Charcot à la Salpêtrière. Le petit volume de cet instrument le rend très maniable et permet de l'appliquer sur tous les points du corps.

Une petite lame de caoutchouc durci de 5 sur 2 centimètres, très légèrement concave, et percée d'un orifice à son centre, sert de base à l'appareil. A l'une de ses extrémités s'élève une tige haute de 5 centimètres environ; sur cette tige monte et descend, au moyen d'une vis de réglage, un tout petit chariot de cuivre, entre les montants duquel oscille, sur un axe transversal C, un cylindre de charbon B, long de 1 cent. 1/2 et épais de 5 millimètres. Au-dessous de ce premier charbon vient aboutir l'extrémité libre d'une mince lame de ressort H, placée horizontalement et fixée par son autre bout à l'extrémité opposée de la planchette de caoutchouc. A ce ressort est adaptée une petite lentille de charbon, qui vient toucher l'extrémité du cylindre oscillant de charbon. Enfin, sous ce premier ressort et parallèlement à lui, comme dans le sphygmographe de M. Marey, se trouve un autre ressort terminé par un bouton explorateur, logué traverse l'orifice de la planchette.

La moindre pression exercée sur ce bouton se transmet par l'intermédiaire des ressorts aux deux contacts de charbon, et fait ainsi varier l'intensité du courant qui les traverse; ces variations sont recueillies par un téléphone que l'observateur applique à son oreille. La mobilité des deux charbons en contact fait comprendre l'extrême sensibilité de ce microphone. Toutefois, il est nécessaire, dans ces expériences, d'obtenir un premier degré de pression initiale, que la vis de réglage peut déjà donner en partie, puisqu'elle permet d'appuyer plus ou moins le cylindre oscillant de charbon sur la lentille inférieure. Mais ceci n'est pas suffisant; car, si l'on explore un pouls un peu ample, les mouvements communiqués aux ressorts soulèveraient brusquement le cylindre supérieur et laboreraient des ruptures de contact.

Nous avons dit à cet inconvénient, dit M. Bondet, de Paris, en plaçant à l'intérieur du petit chariot, au-dessus de l'une des extrémités du cylindre oscillant, un petit morceau de papier couleur plié en forme de V et qui fait office de ressort. Nous n'insisterons pas ici sur l'addition de ce ressort en papier, qui nous appartient et dont les avantages ont déjà été signalés dans plusieurs journaux scientifiques. Nous rappellerons seulement que le papier est un corps très faiblement et très parfaitement élastique, ainsi que l'ont prouvé les expériences de Savart; par conséquent, il se prête beaucoup mieux que l'acier et le caoutchouc aux déplacements et aux rétablissements des contacts de charbon, ou plutôt aux variations de leur pression réciproque. Ainsi constitué, l'appareil, placé sur une artère, indique tous les bruits qui se passent à l'intérieur du vaisseau, et, avec un peu d'habitude, on arrive très aisément à distinguer les différences de rythme, les bruits de souffle, etc. La pulsation est très fortement accentuée, le diccrotisme normal devient perceptible,



Microphone du docteur Bondet, de Paris.

ou même on *entend le tracé du pouls*, tel qu'il est inscrit par le sphygmographe.

Appliqué sur un muscle, le même instrument devient un excellent myophone. Il décèle le bruit des fibres musculaires normal et, lors de la contraction, on entend parfaitement le bruit de ronflement caractéristique de ce phénomène. La tonalité des sons transmis par ce microphone est conservée dans toute sa pureté. On peut facilement s'en convaincre en faisant vibrer successivement près de lui, ou même en contact avec sa planchette, des diapasons de tonalités différentes. Le téléphone répète alors fidèlement la note émise par chacun d'eux, et, ce qui est plus curieux, on peut même distinguer les sons de deux diapasons différents vibrant ensemble, sans que la tonalité de l'un ou de l'autre soit altérée. Nous avons également construit deux autres microphones un peu différents de celui-ci, afin d'étudier la contraction musculaire sur les animaux.

A New Form of Microphone for Physiological Purposes.—Mr. Sidney H. Ravell, of the London Hospital, has devised a form of microphone which promises to effect some of the difficulties experienced in using this class of instrument for examining the pulsations of the heart, &c. Usually the two carbons are both affixed to the membrane connected with the flexible tube. Mr. Raynes' arrangement is to fix the moveable carbon on a rigid stand, whilst the fixed carbon only is attached to the membrane, which is consequently small and very sensitive. Thus, instead of the whole of the microphone vibrating with the pulsations, only the lower block vibrates, and a more accurate record, consequently, is said to be obtained.

A New Use for the Telephone.—Hitherto (says the *Scientific American*) it has been a matter of some difficulty to determine the time of flight of small-arm projectiles owing to the impossibility of seeing them strike. In a series of experiments made by the U.S. Ordnance Department this difficult has been overcome by the use of the telephone. The telephone was connected with two Blake transmitters, one placed near the gun, the other in front of and near the target. The time between the report of the gun and sound of the ball upon the target was measured by a stop-watch. The observations, founded on a large number of experiments, never differed more than a quarter or half of a second from each other, the slight delay in starting the watch being neutralized by the delay in stopping it. It was found that the time of transit was affected by the wind, being shortened by a rear and lengthened by a head wind.

The Battle of the Telephone Companies.—The Edison Telephone Company, fortified by the disclaimer to Edison's telephone patents, have stopped the Indianrubber, Gutta Percha, and Telegraph Works Company (Limited) from making the Blake transmitter for the Telephone Company (Bell's). The Edison Company holds that transmitter to be an infringement of their patents, and they are determined to take steps against any other company making these transmitters. There is no special merit in the Blake transmitter that its users should seriously inconvenience the Bell Company, since Crossley's or any other good microphone will answer just as well. *Electrician*, May 29

LA ENERGÍA ELÉCTRICA.

15 (illegible) (Conclusion.)

Puesto que el trabajo se manifiesta á nosotros, poniendo en libertad á estos gases, el calor desprendido por el circuito, debe hallarse disminuido del que corresponde á este mismo trabajo, lo que en efecto, se confirma por medidas precisas.

La telegrafía se ha aprovechado algunas veces de las propiedades reductrices de la corriente. El aparato de M. L. d'Arlincourt, que hago funcionar á vuestra presencia, descansa, en efecto, sobre la descomposicion eléctrica de una sal, el prusiato amarillo de potasa. Cada vez que el circuito de una pila lejana se cierra, la cinta de papel, impregnada de una solucion incolora de esta sal, sufre una alteracion en el punto preciso en que se halla unida por una punta metálica á la línea exterior. Se forma un azul de Prusia; y una série de corrientes se manifiesta, ya lo veis, por una série correspondiente de puntos azules. Con la ayuda de disposiciones particulares que no puedo exponeros aquí, M. d'Arlincourt ha llegado á reproducir, á través de las mayores distancias, un fac-símile completamente fiel, de un dibujo ó de un autógrafo.

A primera vista, los procedimientos galvanoplásticos, parecen tambien depender de las descomposiciones de las sales metálicas. Y sin embargo, hay que establecer una gran distincion entre estos dos géneros de fenómenos.

La galvanoplastia consiste comunmente en depositar cobre, plata, níkel y oro, sobre sustancias más comunes, á fin de comunicarles la apariencia y las cualidades superficiales de estos metales. No examinaremos aquí la accion pura el cobre. Un baño galvanoplástico se compone esencialmente de una disolucion de sulfato de cobre, en la cual se sumerje por una parte una plancha de cobre, y por otra las superficies que se desean cubrir, con una ligera capa de plombagina, para hacerlas buenas conductoras. Estos son los dos electrodos del baño, es decir, la entrada y la salida de la corriente que le atraviesa en un sentido determinado. Nos encontramos en presencia de dos acciones químicas, que se anulan rigurosamente. En efecto, por una parte el metal se deposita poco á poco sobre el objeto, pero el ácido sulfúrico puesto en libertad sobre á la plaza polar y dá origen á la formacion de una nueva cantidad de sulfato de cobre. El trabajo es, por tanto, nulo en definitiva, puesto que lo que se hace por un lado se destruye por otro. Todo se reduce á un simple trasporte de cobre entre los dos electrodos. Este trasporte no corresponde á ningun gasto de energía. Se podrá decir quizás que constituye el modo de propagacion, de la corriente eléctrica en las condiciones en que nos hemos colocado.

La tercera y última clase de que nos resta ocuparnos, comprende los procedimientos del alumbrado eléctrico. He repetido varias veces en el curso de esta sesion, que la corriente que atraviesa un conductor la calienta. ¿Pero la calienta por igual en todos sus puntos? No ciertamente: allí donde es mayor la resistencia al paso de la corriente, allí es donde se desarrolla la mayor cantidad de calor. La resistencia eléctrica depende de la forma y de la materia de los conductores. Cuando un hilo metálico es de pequeño diámetro, parece constituir una especie de obstáculo al paso de la corriente, obstáculo que puede, sin embargo, compensarse, por las cualidades más ó ménos conductoras de la sustancia de este hilo.

El problema de la luz eléctrica está completamente definido. Primera condicion: hacer de manera que sobre una débil extension de circuito, la resistencia adquiera un valor relativamente considerable. Segunda condicion: no emplear para el conductor destinado á ponerse incandescente sino un cuerpo infusible y que pueda emitir rayos luminosos á la temperatura más baja posible.
